Adult men must absorb only 13 μg of iron/kg of body weight/d (–1 mg/d), whereas menstruating women require about 21 μg/kg (–1.4 mg) per day. In the last two trimesters of pregnancy, requirements increase to about 80 μg/kg (5–6 mg) per day; infants have similar requirements due to their rapid growth (Table 41–4).

The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable. In infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men (see Table 41–2).

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2000). The nonheme fraction represents the larger amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer’s yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. Iron also may be added from cooking in iron pots. In assessing dietary iron intake, it is important to consider not only the amount of iron ingested but also its bioavailability.

### Iron Deficiency

The prevalence of iron deficiency anemia in the U.S. is in the order of 1%–4% and depends on the economic status of the population (McLean et al., 2009). In developing countries, up to 20%–40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas.

The numbers in columns 2 and 3 refer to iron absorption via the GI tract in micrograms per kilogram body weight. As noted in Figure 41–3, of 14.4 mg of dietary iron presented to the GI tract each day, only about 1 mg is absorbed. See text concerning factors influencing iron absorption and differential absorption of heme versus nonheme iron.
for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption (Camaschella, 2015). More severe iron deficiency is usually the result of blood loss, either from the GI tract or, in women, from the uterus. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency. Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast fed or do not receive iron-fortified formula (Finch, 2015). After the age of 2–3 years, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11–18 is insufficient to meet their requirements.

**Treatment of Iron Deficiency**

**General Therapeutic Principles**

The response of iron deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient’s ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption and, with increasing doses of oral iron, limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with moderately severe iron deficiency anemia, tolerable doses of oral iron will deliver, at most, 40–60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4–7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision regarding the effectiveness of treatment should not be made for 3–4 weeks after the start of treatment. An increase of 20 g/L or more in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient’s clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient’s ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3–4 weeks if a favorable response has not occurred.

Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time because the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

**Therapy With Oral Iron**

Orally administered ferrous sulfate is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate, fumarate, succinate, gluconate, aspartate, other ferrous salts, and polysaccharide-ferric hydrate complex are absorbed to approximately the same extent. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have much lower bioavailability. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food. The amount of iron in iron tablets is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Delayed-release preparations are available, but absorption from such preparations varies. Ascorbic acid (≥200 mg) increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with an increase in the incidence of side effects. Preparations that contain other compounds with therapeutic action, such as vitamin B12, folate, or cobalt, are not recommended because the patient’s response to the combination cannot easily be interpreted.

The average dose for the treatment of iron deficiency anemia is about 200 mg of iron per day (2–3 mg/kg), given in three equal doses of 65 mg. Children weighing 15–30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron (e.g., 5 mg/kg). When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15 to 30 mg of iron per day are adequate. Bioavailability of iron is reduced with food and by concurrent antacids. For a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day.

The duration of treatment is governed by the rate of recovery of hemoglobin (Table 41–5) and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red cell mass usually is reconstituted within 1–2 months. Thus, an individual with a hemoglobin of 50 g/L per liter may achieve a normal complement of 150 g/L in about 50 days, whereas an individual with a hemoglobin of 100 g/L may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3–4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

**Untoward Effects of Oral Preparations of Iron.** Side effects of oral iron preparations include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate

</table>
therapy at a small dosage and then gradually to increase the dosage to that desired. Only individuals with underlying disorders that augment the absorption of iron run the hazard of developing iron overload (hemochromatosis).

**Iron Poisoning.** Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1–2 g of iron may cause death, but 2–10 g usually is ingested in fatal cases. All iron preparations should be kept in childproof bottles. Signs and symptoms of severe poisoning may occur within 30 min after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 h, there may be a transient period of apparent recovery, followed by death in 12–24 h. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring.

In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and determination of the concentration of iron in plasma can be performed. If the latter is less than 63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an X-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg/L), deferoxamine should be administered (see Chapter 71). The speed of diagnosis and therapy is important. With early treatment, the mortality from iron poisoning can be reduced from 45% to about 1%. Deferiprone and deferasirox are oral iron chelators approved by the FDA for treatment of patients with thalassemia who have iron overload.

**Therapy With Parenteral Iron**

When oral iron therapy fails, parenteral iron administration may be an effective alternative. Common indications are iron malabsorption (e.g., sprue, short-bowel syndrome), severe iron intolerant, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin. Parenteral iron can be given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. The indications for parenteral iron therapy include documented iron deficiency and intolerance or responsiveness to oral iron.

The rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1–3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Parenteral iron therapy should be used only when clearly indicated because acute hypersensitivity; including anaphylactic and anaphylactoid reactions, can occur. Other reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and, in some patients with rheumatoid arthritis, exacerbation of the disease.

Several iron formulations are available in the U.S. (Larson and Coyne, 2014). These include iron dextran, sodium ferric gluconate, ferumoxytol, iron sucrose, and ferric carboxymaltose. Ferumoxytol is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle approved for treatment of iron deficiency anemia in patients with chronic kidney disease; the ferumoxytol has to be administered safely as a 1.02-g infusion over a relatively short infusion time of 15 min (Auerbach et al., 2013). Indications for ferric gluconate and iron sucrose are limited to patients with chronic kidney disease and documented iron deficiency; although broader applications are being advocated (Larson and Coyne, 2014).

**Iron Dextran.** Iron dextran injection is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight ~ 180,000 Da) that contains 50 mg/mL of elemental iron. The use of low-molecular-weight iron dextran has reduced the incidence of toxicity relative to that observed with high-molecular-weight preparations. Iron dextran can be administered by intravenous (preferred) or intramuscular injection. Injection of a therapeutic dose should be initiated only after a test dose of 0.5 mL (25 mg of iron). Given intravenously in a dose less than 500 mg, the iron dextran complex is cleared with a plasma t½ of 6 h. When 1 g or more is administered intravenously as total-dose therapy, reticuloendothelial cell clearance is constant at 10–20 mg/h.

Intramuscular injection of iron dextran should be initiated only after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing less than 4.5 kg, 1 mL (50 mg of iron) for children weighing less than 9 kg, and 2 mL (100 mg of iron) for other patients. However, local reactions and the concern about malignant change at the site of injection make intramuscular administration inappropriate except when the intravenous route is inaccessible. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Use iron dextran with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

With multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss, accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 μg/L.

**Sodium Ferric Gluconate.** Sodium ferric gluconate is an intravenous iron preparation with a molecular size of about 295 kDa and an osmolality of 990 mOsm/kg. Administration of ferric gluconate at doses ranging from 62.5 to 125 mg during hemodialysis is associated with transferrin saturation exceeding 100%. Unlike iron dextran, which requires processing by macrophages that may require several weeks, about 80% of sodium ferric gluconate is delivered to transferrin within 24 h. Sodium ferric gluconate also has a lower risk of inducing serious anaphylactic reactions than iron dextran (Sengolge et al., 2005).

**Iron Sucrose.** Iron sucrose is a complex of polynuclear iron (III)–hydroxide in sucrose (Begin and Jaspers, 2014). Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. Iron sucrose is generally administered in daily amounts of 100–200 mg within a 14-day period to a total cumulative dose of 1000 mg. Like sodium ferric gluconate, iron sucrose appears to be better tolerated and to cause fewer adverse events than iron dextran (Hayat, 2008). This agent is FDA-approved for the treatment of iron deficiency in patients with chronic kidney disease. Chronic use has the potential to cause renal tubulointerstitial damage (Agarwal, 2006).

**Ferric Carboxymaltose.** Ferric carboxymaltose is an iron complex consisting of a ferric hydroxide core and a carbohydrate shell (Keating, 2015). With this preparation, a replenishment dose of up to 1000 mg of iron can be administered in 15 min. Intra-venous administration results in transient elevations in serum iron, serum ferritin, and transferrin saturation, with subsequent correction in hemoglobin levels and replenishment of depleted iron stores. Ferric carboxymaltose is rapidly cleared from the circulation, becoming distributed (~80%) in the marrow, as well as the liver and spleen. Common reported drug-related adverse effects include headache, dizziness, nausea, abdominal pain, constipation, diarrhea, rash, and injection site reactions. However, the incidence of drug-related adverse events appears similar to those of patients treated with oral ferrous sulfate.
Ferric carboxymaltose is FDA-approved for therapy of iron deficiency anemia.

**Copper, Pyridoxine, and Riboflavin**

**Copper**

Copper has redox properties similar to those of iron, which simultaneously are essential and potentially toxic to the cell. Cells have virtually no free copper. Instead, copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of its redox properties. Transfer of copper to nascent cuproenzymes is performed by individual or collective activities of P-type ATPases, ATP7A, and ATP7B, which are expressed in all tissues (Nevitt et al., 2012). In mammals, the liver is the organ most responsible for the storage, distribution, and excretion of copper. Mutations in ATP7A or ATP7B that interfere with this function have been found responsible for Wilson disease or Menkes syndrome (steely hair syndrome) (de Bie et al., 2007), respectively, which can result in life-threatening hepatic failure.

Copper deficiency is extremely rare; the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. Even in clinical states associated with hypopurpuraemia (scurvy, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anaemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery, in those who are receiving parenteral nutrition, in malnourished infants, and in patients ingesting excessive amounts of zinc (Willis et al., 2005). Copper deficiency interferes with the absorption of iron and its release from reticuloendothelial cells. In humans, the prominent findings have been leucopenia, particularly granulocytopenia, and anaemia. Concentrations of iron in plasma are variable, and the anaemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leucopenia and anaemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1–2 mg per day may be added to the solution of nutrients for parental administration.

**Pyridoxine**

Patients with either hereditary or acquired sideroblastic anemia characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ-aminolevulinate synthase.

Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antibiotics drugs isoniazid and pyrazinamide, which act as vitamin B_{6} antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (see Chapter 56). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead. Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anaemia require prolonged therapy with large doses of the vitamin, 50–500 mg/d. The occasional patient who is refractory to oral pyridoxine may respond to parenteral administration of pyridoxal phosphate. However, oral pyridoxine in doses of 200–300 mg per day produces intracellular concentrations of pyridoxal phosphate equal to or greater than those generated by therapy with the phosphorylated vitamin.

**Riboflavin**

The spontaneous appearance in humans of red cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. Riboflavin deficiency has been described in combination with infection and protein deficiency, both of which are capable of producing hypoproliferative anaemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

**Vitamin B_{12}, Folic Acid, and the Treatment of Megaloblastic Anemias**

Vitamin B_{12} and folic acid are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins.

**Cellular Roles of Vitamin B_{12} and Folic Acid**

The major roles of vitamin B_{12} and folic acid in intracellular metabolism are summarized in Figure 41-4. Intracellular vitamin B_{12} is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin. Methylcobalamin (CH_{3}B_{12}) supports the methionine synthetase reaction, which is essential for normal metabolism of folate (Weissbach, 2008). Methyl groups contributed by methyltetrahydrofolate (CH_{3}H_{4}PteGlu_{t}) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate-cobalamin interconversion is pivotal for normal peripheral and brain development, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product SAM, the maintenance of a number of methylation reactions.

Deoxyadenosylcobalamin (deoxyadenosyl B_{12}) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of l-methylmalonyl CoA to succinyl CoA, an important reaction in cellular metabolism.
carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate.

Because methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate (H₄PteGlu). Tetrahydrofolate is a precursor for the formation of intracellular polyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate (5,10-CH₂H₄PteGlu). The last derivative donates the methylene group to dUMP for the synthesis of dTMP—an extremely important reaction in DNA synthesis. In the process, the 5,10-CH₂H₄PteGlu is converted to dihydrofolate (H₂PteGlu). The cycle then is completed by the reduction of the H₂PteGlu to H₄PteGlu by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 66).

Deficiency of either vitamin B₁₂ or folate decreases the synthesis of methionine and SAM and consequently interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate. This tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B₁₂ deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 41–4). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B₁₂ to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B₁₂ or folate acid.

The mechanisms responsible for the neurological lesions of vitamin B₁₂ deficiency are less well understood (Solomon, 2007). Damage to the myelin sheath is the most obvious lesion in vitamin B₁₂ deficiency (see Chapter 66). As shown in Figure 41–4, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of FIGLU and purines and pyrimidines.

Deficiency of either vitamin B₁₂ or folate decreases the synthesis of methionine and SAM and consequently interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate. This tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B₁₂ deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 41–4). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B₁₂ to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B₁₂ or folate acid.

The mechanisms responsible for the neurological lesions of vitamin B₁₂ deficiency are less well understood (Solomon, 2007). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl B₁₂-dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of supply of methylmalonyl CoA synthase and the block of the conversion of methionine to SAM are more likely to be responsible.

**Vitamin B₁₂ and Human Health**

Humans depend on exogenous sources of vitamin B₁₂ (see structure in Figure 41–5). In nature, the primary sources are certain microorganisms that grow in soil or the intestinal lumen of animals that synthesize the vitamin. The daily nutritional requirement of 3–5 μg must generally be obtained from animal by-products in the diet. However, some vitamin B₁₂ is available from legumes, which are contaminated with bacteria that can synthesize vitamin B₁₂ and vegetarians often fortify their diets with a wide range of vitamins and minerals; thus, strict vegetarians rarely develop vitamin B₁₂ deficiency. The terms vitamin B₁₂ and cyanocobalamin are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin because only these derivatives remain active after storage.

**Metabolic Functions.** The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative S-adenosylmethionine. In addition, when concentrations of vitamin B₁₂ are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid. The hematologic abnormalities in vitamin B₁₂-deficient patients result from this process. Deoxyadenosylcobalamin is required for the rearrangement of methylmalonyl CoA to succinyl CoA.

**ADME and Daily Requirements**

In the presence of gastric acid and pancreatic proteases, dietary vitamin B₁₂ is released from food and salivary-binding protein and bound to gastric intrinsic factor. When the vitamin B₁₂–intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Vitamin B₁₂ deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 41–6). Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. Several intestinal conditions can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretions), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Absorbed vitamin B₁₂ binds to transcobalamin II, a plasma β globulin, for transport to tissues. The supply of vitamin B₁₂ available for tissues is

---

**Figure 41–4** Interrelationships and metabolic roles of vitamin B₁₂ and folic acid. See text for explanation and Figure 41–5 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II.
Adequate supply of folic acid as CH$_3$-H$_2$NOCH$_2$CN is crucial for the formation of methylcobalamin, requiring normal transport into cells and an adequate supply of transcobalamin II. The utility of measurements of vitamin B$_12$ concentration for evaluating hepatic stores by interference with reabsorption of vitamin B$_12$ is limited in certain conditions, such as (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of transcobalamin II; or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B$_12$, which is not destined for reabsorption. Interference with reabsorption by intestinal disease can progressively deplete hepatic stores of vitamin B$_12$.

**Vitamin B$_12$ Deficiency**

The plasma concentration of vitamin B$_12$ is the best routine measure of B$_12$ deficiency and normally ranges from 150 to 660 pM (~200–900 pg/mL). Deficiency should be suspected whenever the concentration falls below 150 pM. The correlation is excellent except when the plasma concentrations of vitamin B$_12$ are below 100 pM. In the Schilling test, the anemia will respond to parenteral doses of vitamin B$_12$, and the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease. Vitamin B$_12$ deficiency can irreversibly damage the nervous system. Because the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B$_12$ deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic (Spence, 2016).

**Vitamin B$_12$ Therapy**

Vitamin B$_12$ has an undeserved reputation as a health tonic and has been used for a number of disease states. A number of multivitamin...
preparations are marketed either as nutritional supplements or for the treatment of anemia; many are supplemented with intrinsic factor. Although the combination of oral vitamin B₁₂ and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable.

Vitamin B₁₂ is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Oral administration cannot be relied on for effective therapy in the patient with a marked deficiency of vitamin B₁₂ and abnormal hematopoiesis or neurological deficits. The treatment of choice for vitamin B₁₂ deficiency is cyanocobalamin administered by intramuscular or subcutaneous injection, never intravenously. Cyanocobalamin is administered in doses of 1–1000 μg. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II. Doses greater than 100 μg are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin B₁₂ will not result in greater retention of the vitamin. Administration of 1000 μg is of value in the performance of the Schilling test. After isotopically labeled vitamin B₁₂ is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 μg of cyanocobalamin is administered intramuscularly. This unlabelled material saturates the transport system and tissue binding sites, so more than 90% of the labeled and unlabeled vitamin is excreted during the next 24 h.

Effective use of the vitamin B₁₂ depends on accurate diagnosis and an understanding of the following general principles of therapy:

- Vitamin B₁₂ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist (i.e., dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B₁₂ in patients who have had a gastrectomy, and certain diseases of the small intestine) (Del Villar Madrigal et al., 2015). When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B₁₂, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.
- The relative ease of treatment with vitamin B₁₂ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by macrocytic anemia or an unexplained neuropsychiatric disorder.
- Therapy always should be as specific as possible. Although a large number of multivitamin preparations are available, the use of shot gun vitamin therapy in the treatment of vitamin B₁₂ deficiency can be dangerous: Sufficient folic acid may be given to result in a hematologic recovery that can mask continued vitamin B₁₂ deficiency and permit neurological damage to develop or progress.
- Although a classical therapeutic trial with small amounts of vitamin B₁₂ can help confirm the diagnosis, acutely ill elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B₁₂ to guarantee rapid recovery.
- Long-term therapy with vitamin B₁₂ must be evaluated at intervals of 6–12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

**Treatment of the Acutely Ill Patient.** The therapeutic approach depends on the severity of the illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or neurological signs or symptoms, the administration of vitamin B₁₂ alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of GI function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin B₁₂ (1–10 μg per day) can confirm the presence of an uncomplicated vitamin B₁₂ deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. Effective therapy must not wait for detailed diagnostic tests. Once the megaloblastic erythropoiesis has been confirmed and sufficient blood collected for later measurements of vitamin B₁₂ and folic acid, the patient should receive intramuscular injections of 100 μg of cyanocobalamin and 1–5 μg of folic acid. For the next 1–2 weeks, the patient should receive daily intramuscular injections of 100 μg of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red cell mass will not occur for 10–20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2–3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

The first objective of hematologic change is the disappearance of the megaloblastic morphology of the marrow. As the ineffective erythropoiesis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin, usually within the first 48 h. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3–5 days later. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore, it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is below 35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow. The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.

**Long-Term Therapy With Vitamin B₁₂** Once begun, vitamin B₁₂ therapy must be maintained for life. This fact must be impressed on the patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin.

Intramuscular injection of 100 μg of cyanocobalamin every 4 weeks is usually sufficient. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin B₁₂ in the period immediately after the diagnosis. Doses of 100 μg per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin B₁₂ concentrations in plasma and to obtain peripheral blood counts at intervals of 3–6 months to confirm the adequacy of therapy. Because refractoriness to therapy can develop at any time, evaluation must continue throughout the patient’s life. Intranasal preparations are available for maintenance following normalization of vitamin B₁₂-deficient patients without nervous system involvement.

**Folic Acid and Human Health**

**Biochemical Roles of Folate**

**Pteroylglutamic acid** (Figure 41–7) is the common pharmaceutical form of folic acid. It is not the principal folate congener in food or the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-member ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 41–4, and each plays a specific role in intracellular metabolism:

- **Conversion of Homocysteine to Methionine.** This reaction requires CH₃H₄PteGlu as a methyl donor and uses vitamin B₁₂ as a cofactor.
- **Conversion of Serine to Glycine.** This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and uses pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH₂H₄PteGlu, an essential coenzyme for the synthesis of dTMP.
- **Synthesis of Thymidylate.** 5,10-CH₂H₄PteGlu donates a methylene group and reducing equivalents to dUMP for the synthesis of dTMP—a rate-limiting step in DNA synthesis.
Histidine Metabolism. H$_4$PteGlu also acts as an acceptor of a formimino group in the conversion of FIGLU to glutamic acid.

Synthesis of Purines. Two steps in the synthesis of purine nucleotides require the participation of 10-CHOH$_3$PteGlu as a formyl donor in reactions catalyzed by ribotide transformylases: the formylation of glycaminide ribonucleotide and the formylation of 5-aminimidazole-4-carboxamide ribonucleotide. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.

Utilization or Generation of Formate. This reversible reaction uses H$_4$PteGlu and 10-CHOH$_3$PteGlu.

Daily Requirements. Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food. Generally, a standard U.S. diet provides 50–500 μg of absorbable folate per day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg per day. In the normal adult, the recommended daily intake is 400 μg; pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500–600 μg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 μg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine.

ADME. As with vitamin B$_12$, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 41–8). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a pteroylglutamyl carboxypeptidase associated with mucosal cell membranes. The mucosa of the duodenum and upper part of the jejunum are rich in dihydrofolate reductase and can methylate most or all of the reduced folate that is absorbed. Because most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprues are common causes of folate deficiency and megaloblastic anemia.

Once absorbed, folate is transported rapidly to tissues as CH$_3$H$_4$PteGlu. Although certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogues. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain disease states, such as uremia, cancer, and alcoholism. A constant supply of CH$_3$H$_4$PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H$_4$ or H$_3$PteGlu) and then transports the CH$_3$H$_4$PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide 200 μg or more of folate each day for recirculation to tissues. The importance of the enterohepatic cycle was suggested by animal studies that showed a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of CH$_3$H$_4$PteGlu from hepatic parenchymal cells.

**Folate Deficiency.** Folate deficiency is a common complication of diseases of the small intestine that interferes with the absorption of folate.
Dietary supplementation is necessary when there is a requirement that therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of vitamin B<sub>12</sub>, deficiency, and these may progress and become irreversible.

**Therapeutic Use of Folate.** Folic acid is marketed as oral tablets containing PteGlu or 1-methylfolate, as an aqueous solution for injection (5 mg/mL), and in combination with other vitamins and minerals. Folic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (see Chapter 66). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. Folic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency.

Evaluation of the serum folate level can help exclude folate deficiency, but only in patients whose serum folate levels exceed 5.0 ng/mL; 2%–5% of healthy adults can have serum folate levels that are below this level. Red cell folate levels (reference range > 140 ng/mL) reflect chronic folate levels, are less affected by acute ingestion of folate than are serum levels, but are more time consuming and costly to measure. Serum folate concentrations more frequently show a higher correlation with serum homocysteine, which is a sensitive marker of deficiency (Farrell et al., 2013). In any case, a patient with a low serum or red cell folate level should have follow-up tests that include serum homocysteine (reference range 5–16 mmol/L), which is elevated in B<sub>12</sub> and folate deficiency, and serum methyhyalonic acid (reference range 70–270 mmol/L), which is elevated only in B<sub>12</sub> deficiency. Untoward Effects. There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. Oral folic acid usually is not toxic. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone and increase the frequency of seizures in susceptible children. The FDA recommends that oral tablets of folic acid be limited to strengths of 1 mg or less.

Endocrinology and Hormones: General Concepts

Endocrinology analyzes the biosynthesis of hormones, their sites of production, and the sites and mechanisms of their action and interaction. The term hormone is of Greek origin and classically refers to a chemical messenger that circulates in body fluids and produces specific effects on cells distant from the hormone’s point of origin. The major functions of hormones include the regulation of energy storage, production, and utilization; the adaptation to new environments or conditions of stress; the facilitation of growth and development; and the maturation and function of the reproductive system. Although hormones were originally defined as products of ductless glands, we now appreciate that many organs not classically considered as “endocrine” (e.g., the heart, kidneys, GI tract, adipocytes, and brain) synthesize and secrete hormones that play key physiological roles. In addition, the field of endocrinology has expanded to include the actions of growth factors acting by means of autocrine and paracrine mechanisms, the influence of neurons—particularly those in the hypothalamus—that regulate endocrine function, and the reciprocal interactions of cytokines and other components of the immune system with the endocrine system.

Conceptually, hormones may be divided into two classes:

- Hormones that act predominantly via nuclear receptors to modulate transcription in target cells (e.g., steroid hormones, thyroid hormone, and vitamin D)
- Hormones that typically act via membrane receptors to exert rapid effects on signal transduction pathways (e.g., peptide and amino acid hormones)

The receptors for both classes of hormones provide tractable targets for a diverse group of compounds that are among the most widely used drugs in clinical medicine.

The Hypothalamic-Pituitary-Endocrine Axis

Many of the classic endocrine hormones (e.g., cortisol, thyroid hormone, sex steroids, GH) are regulated by complex reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (Table 42–1). The basic organization of the hypothalamic-pituitary-endocrine axis is summarized in Figure 42–1. Discrete sets of hypothalamic neurons produce different releasing and inhibiting hormones, which are axonally transported to the median eminence. On stimulation, these neurons secrete their respective hypothalamic hormones into the hypothalamic-adenohypophysial portal veins, which connect to the anterior pituitary gland. The hypothalamic hormones bind to membrane receptors on specific subsets of pituitary cells and regulate the secretion of the corresponding pituitary hormones. The pituitary hormones, which can be thought of as the master signals, circulate to the target endocrine glands or other tissues, where they activate specific receptors to stimulate the synthesis and secretion of the target endocrine hormones or exert other tissue-specific effects. These interactions are feed-forward regulation in which the master (signal) hormones stimulate the production of target hormones by the endocrine organs. Superimposed on this positive feed-forward regulation is negative feedback regulation, which permits precise control of hormone levels (see Figures 42–2 and 42–6). Typically, the endocrine target hormone circulates to both the hypothalamus and pituitary, where it acts via specific receptors to inhibit the production and secretion of both its hypothalamic-releasing hormone and the regulatory pituitary hormone. In addition, other brain regions have inputs to the hypothalamic hormone–producing neurons, further integrating the regulation of hormone levels in response to diverse stimuli.

Abbreviations

AC: adenyl cyclase
ACTH: corticotropin, formerly adrenocorticotrophic hormone
CG: choriionic gonadotropin
CRH: corticotropin-releasing hormone
DA: dopamine
FSH: follicle-stimulating hormone, follitropin
GH: growth hormone
GHRH: growth hormone–releasing hormone
GnRH: gonadotropin-releasing hormone
GPCR: G protein –coupled receptor
hCG: human chorionic gonadotropin
5HT: 5-hydroxytryptamin serotonin
IGF: insulin-like growth factor
IGFBP: IGF-binding protein
IRS: insulin receptor substrate
LH: luteinizing hormone; lutropin
NPY: neuropeptide Y
OXTR: oxytocin receptor
POMC: pro-opiomelanocortin
PRL: prolactin
SC: subcutaneous
SHC: Src homology-containing protein
SHP2: Src-homology-2-domain-containing protein tyrosine phosphatase 2
SST: somatostatin
SSTR: SST receptor
TRH: thyrotropin-releasing hormone
TSH: thyroid-stimulating hormone, thyrotropin
VIP: vasoactive intestinal peptide

Pituitary Hormones and Their Hypothalamic-Releasing Factors

The anterior pituitary hormones can be classified into three different groups based on their structural features (Table 42–2):

- POMC-derived hormones include corticotropin (ACTH) and α-MSH. These are derived from POMC by proteolytic processing (see Chapters 20 and 46).
- Somatotropic family of hormones include GH and PRL. In humans, the somatotropic family also includes placental lactogen.
- The glycoprotein hormones—TSH (also called thyrotropin), LH (also called lutropin), and FSH (also called follitropin). In humans, the glycoprotein hormone family also includes hCG.

The synthesis and release of anterior pituitary hormones are influenced by the CNS. Their secretion is positively regulated by a group of peptides referred to as hypothalamic-releasing hormones (see Figure 42–1).
These include CRH, GHRH, GnRH, and TRH. SST, another hypothalamic peptide, negatively regulates secretion of pituitary GH and TSH. The neurotransmitter DA inhibits the release of GH by acting at the hypothalamus and the pituitary. The actions of GH can be direct or indirect (mediated by IGF-1). See text for discussion of the other agents that modulate GH secretion and of the effects of locally produced IGF-1. Inhibition, −; stimulation, +.

These peptides are derived by proteolytic processing of the common precursor, POMC.

Receptors for these hormones belong to the cytokine superfamily.

These are heterodimeric glycoproteins with a common α subunit of 92 amino acids and unique β subunits that determine biological specificity and t½.

*See Chapter 46 for further discussion of POMC-derived peptides, including ACTH and α-MSH.
The amplitude of secretory pulses is greatest at night. GH secretion is stimulated by GHRH and ghrelin and subject to feedback inhibition by GH itself, SST, and IGF-1 (Figure 42–2).

**Growth Hormone–Releasing Hormone.** GHRH, a peptide with 44 amino acids produced by hypothalamic neurons, stimulates GH secretion (see Figure 42–2) by binding to a specific GPCR on somatotropes in the anterior pituitary. The stimulated GHRH receptor couples to G, to raise intracellular levels of cAMP and Ca, thereby stimulating GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of short stature in humans.

**Ghrelin.** Ghrelin, a 28-amino-acid peptide, stimulates GH secretion through actions on a GPCR called the GH secretagogue receptor. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach but also is produced at lower levels at a number of other sites, including the pituitary and hypothalamus. Hypothalamic ghrelin is thought to be a stimulus for GH release through actions on pituitary somatotrophs and hypothalamic GHRH-secreting neurons.

Both fasting and hypoglycemia increase circulating stomach-derived ghrelin levels, and this, in turn, stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. The role of stomach-derived ghrelin in GH secretion is unclear because clinical studies attempting to correlate circulating levels of ghrelin with GH secretion have produced conflicting results (Nass et al., 2011).

**Other Stimuli.** Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH or SST and thereby affect GH secretion. DA, 5HT, and adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, glucose, IGF-1, and GH itself inhibit release. Many of the physiological factors that influence PRL secretion also affect GH secretion. Thus, sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

**Feedback Control of GH Secretion.** Growth hormone and its major peripheral effectors, IGF-1, act in negative-feedback loops to suppress GH secretion (Figure 42–2).

**Insulin-like Growth Factor 1.** The negative effect of IGF-1 is predominantly direct effects on the anterior pituitary gland but also at the hypothalamus via stimulation of SST secretion. The negative-feedback action of GH is mediated in part by SST, synthesized in more widely distributed neurons (Ergun-Longmire and Wajnrajch, 2013).

After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. The type I IGF receptor is closely related to the insulin receptor and consists of a heterotrimer with intrinsic tyrosine kinase activity. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity; insulin also can activate the type I IGF receptor but with an affinity approximately two orders of magnitude less than that of the IGFs. The signal transduction pathway for the insulin receptor is described in detail in Chapter 47.

**Somatostatin.** Somatostatin is synthesized as a 92-amino-acid precursor and processed by proteolytic cleavage to generate two peptides: SST-28 and SST-14 (Figure 42–3). SST exerts its effects by binding to and activating a family of five related GPCRs that signal through G to inhibit cAMP formation and to activate K channels and protein phosphotyrosine phosphatases.

There are five SST receptor subtypes. SST binds the two forms of SST with approximately equal affinity; SST, has a 10- to 15-fold greater affinity for SST-28, SST, and SST. All these receptors mediate the major regulation of GH secretion, and recent studies suggested that these two SSTs mediates the same signal through a common G protein. SST exerts direct effects on somatotrophs in the pituitary and different effects mediated via GHRH receptors in the arcuate nucleus.

**PRL Secretion**

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of PRL secretion is DA, which interacts with the D, receptor, a GPCR on lactotropes, to inhibit PRL secretion (Figure 42–4). TRH and hypothalamic VIP have PRL-releasing properties, but their physiologic significance is uncertain. PRL acts predominantly in women, both during pregnancy and in the postpartum period in women who breastfeed. During pregnancy, the maternal serum PRL level starts to increase at 8 weeks of gestation, peaks to 150–250 ng/ml at term, and declines thereafter to prepregnancy levels unless the mother breastfeeds the infant. Suckling or breast manipulation in nursing mothers transmits signals from the breast to the hypothalamus via the spinal cord and the median forebrain bundle, causing elevation of circulating PRL levels. PRL levels can rise 10-fold within 30 min of stimulation. This response is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The suckling response becomes less pronounced after several months of breastfeeding, and PRL concentrations eventually decline to prepregnancy levels. PRL also is synthesized by decidual cells early in pregnancy (accounting for the high levels of PRL in amniotic fluid during the first trimester of human pregnancy).

**Figure 42–3** Structures of SST-14 and selected synthetic analogues. Residues that play key roles in binding to SST receptors are shown in red. Octreotide, lanreotide, and pasireotide are clinically available synthetic analogues of SST. Apo, [2-aminoethoxyaminocarbonyl oxy]-t-proline; D-Nal, 3-(2-naphthyl)- D-alanyl; PGly, phenylglycine; BTyr, benzyltyrosine.
Molecular and Cellular Bases of GH and PRL Action

All of the effects of GH and PRL result from their interactions with specific membrane receptors on target tissues (Figure 42–5). Receptors for GH and PRL belong to the cytokine receptor superfamily and thus share structural similarity with the receptors for leptin, erythropoietin, granulocyte-macrophage colony-stimulating factor, and several of the interleukins. These receptors contain an extracellular hormone-binding domain, a single membrane-spanning region, and an intracellular domain that mediates signal transduction.

Growth hormone receptor activation results in the binding of a single GH to two receptor monomers to form a GH-[GHR], ternary complex (initiated by high-affinity interaction of GH with one monomer of the GHR dimer [mediated by GH site 1], followed by a second, lower-affinity interaction of GH with the other GHR [mediated by GH site 2]). These interactions induce a conformational change that activates downstream signaling. The ligand-occupied GHR dimer lacks inherent tyrosine kinase activity but provides docking sites for two molecules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of the JAK2 molecules leads to trans-phosphorylation and autoactivation of JAK2, with consequent tyrosine phosphorylation of docking sites on the cytoplasmic segments of the GHR and of cytoplasmic proteins that mediate downstream signaling events (Figure 42–5; Chia, 2014). These include STAT proteins, SHC (an adapter protein that regulates the Ras/MAPK signaling pathway), and IRS-1 and IRS-2 (proteins that activate the PI3K pathway). One critical target of STAT5 is the gene encoding IGF-1, a mediator of many of the effects of GH (Figure 42–2). The fine control of GH action also involves feedback regulatory events that subsequently turn off the GH signal. As part of its action, GH induces the expression of a family of suppressor of cytokine signaling (SOCS) proteins and a group of protein tyrosine phosphatases (including SHP2) that, by different mechanisms, disrupt the communication of the activated GHR with JAK2 (Flores-Morales et al., 2006).

Pegvisomant is a GH analogue with amino acid substitutions that disrupt the interaction at site 2; pegvisomant binds to the receptor and causes its internalization but cannot trigger the conformational change that stimulates downstream events in the signal transduction pathway.

The effects of PRL on target cells also result from interactions with a cytokine family receptor that is widely distributed and signals through many of the same pathways as the GHR (Bernard et al., 2015). Alternative splicing of the PRL receptor gene on chromosome 5 gives rise to multiple forms of the receptor that are identical in the extracellular domain but differ in their cytoplasmic domains. In addition, soluble forms that correspond to the extracellular domain of the receptor are found in circulation. Unlike human GH and placental lactogen, which also bind to the PRL receptor and thus are lactogenic, PRL binds specifically to the PRL receptor and has no somatotropic (GH-like) activity.

Physiological Effects of GH and PRL

The most striking physiological effect of GH is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after the epiphyses have closed. GH also increases muscle mass, increases the glomerular filtration rate, and stimulates preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral tissues (e.g., adipocytes and muscle) that decrease glucose utilization and increase lipolysis, but most of its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1. IGF-1 interacts with receptors on the cell surface that mediate its biological activities. Circulating IGF-1 is associated with a family of binding proteins (IGFBP) that serve as transport proteins and also may mediate certain aspects of IGF-1 signaling. Most IGF-1 in circulation is bound to IGFBP-3 and another protein called the acid-labile subunit. The essential role of IGF-1 in growth is evidenced by patients with loss-of-function mutations in both alleles of the IGF1 gene, whose severe intrauterine and postnatal growth retardation is unresponsive to GH but responsive to recombinant human IGF-1, and by the association of mutations in the IGF-1 receptor with intrauterine growth retardation (Walenkamp and Wit, 2008).

Figure 42–5 Mechanisms of GH and PRL action and of GHR antagonism. A. GH and two GHRs form a ternary complex that induces association and Tyr autophosphorylation of JAK2 and of docking sites on the cytoplasmic tail of GHRs. JAK2 phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of MAPK, which ultimately modulate gene expression. The structurally related PRL receptor also is a ligand-activated homodimer that recruits the JAK-STAT signaling pathway. GH also activates IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. B. Pegvisomant, a recombinant pegylated variant of human GH, is a high-affinity GH antagonist that interferes with GH binding.
CHAPTER 42
INTRODUCTION TO ENDOCRINOLOGY: THE HYPOTHALAMIC-PITUITARY AXES

The PRL effects are limited primarily to the mammary gland, where PRL plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelia and is essential for lactation. Target genes, by which PRL induces mammary development, include those encoding milk proteins (e.g., caseins and whey acidic protein), genes important for intracellular structure (e.g., keratins), and genes important for cell-cell communication (e.g., amphiregulin). PRL receptors are present in many other sites, including the hypothalamus, liver, adrenal, testes, ovaries, prostate, and immune system, suggesting that PRL may play multiple roles outside the breast. The physiological effects of PRL at these sites remain poorly characterized.

Pathophysiology of GH and PRL
Distinct endocrine disorders result from either excessive or deficient GH production. In contrast, PRL predominantly affects endocrine function when produced in excess.

Excess Production
Syndromes of excess secretion of GH and PRL typically are caused by somatotrope or lactotrope adenomas that oversecrete the respective hormones. These adenomas often retain some features of the normal regulation described previously, thus permitting pharmacological modulation of secretion—an important modality in therapy.

Clinical Manifestations of Excess GH. GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis often is delayed. Mortality is increased at least 2-fold relative to age-matched controls, predominantly due to increased death from cardiovascular disease. Treatments that normalize GH and IGF-1 levels reverse this increased risk of mortality and ameliorate most of the other symptoms and signs.

Clinical Manifestations of Excess Prolactin. Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothroidism associated with increased TRH levels, or from treatment with DA receptor antagonists. Most often, hyperprolactinemia is caused by PRL-secreting pituitary adenomas. Manifestations of PRL excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, erectile dysfunction, and infertility.

Diagnosis of Growth Hormone and Prolactin Excess. Although acromegaly should be suspected in patients with the appropriate symptoms and signs, diagnostic confirmation requires the demonstration of increased circulating GH or IGF-1. The "gold standard" diagnostic test for acromegaly is the oral glucose tolerance test. Whereas normal subjects suppress their GH level to less than 1 ng/mL in response to an oral glucose challenge, the absolute value may vary depending on the sensitivity of the assay, patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

In patients with hyperprolactinemia, the major question is whether conditions other than a PRL-producing adenoma are responsible for the elevated PRL level. A number of medications that inhibit DA signaling can cause moderate elevations in PRL (e.g., antipsychotics, metoclopramide), as can primary hypothroidism, pituitary mass lesions that interfere with DA delivery to the lactotropes, and pregnancy. Thus, thyroid function and pregnancy tests are indicated, as is MRI to look for a pituitary adenoma or other defect that might elevate serum PRL.

Impaired Production
Clinical Manifestations of Growth Hormone Deficiency. Children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. GH deficiency in adults is associated with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes. The diagnosis of GH deficiency should be entertained in children with height more than 2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height. In adults, overt GH deficiency usually results from pituitary lesions caused by a functioning or nonfunctioning pituitary adenoma, secondary to trauma, or related to surgery or radiotherapy for a pituitary or suprasellar mass (Ergun-Longmire and Wajnrajch, 2013). Almost all patients with multiple deficits in other pituitary hormones also have deficient GH secretion.

Clinical Manifestations of Prolactin Deficiency. PRL deficiency may result from conditions that damage the pituitary gland. Inasmuch as the sole clinical manifestation of PRL deficiency is failure of postpartum lactation, PRL is not given as part of endocrine replacement therapy.

Pharmacotherapy of Disorders GH and PRL

Treatment of Growth Hormone Excess
The initial treatment modality in gigantism/acromegaly is selective removal of the adenoma by transsphenoidal surgery. Radiation and drugs that inhibit GH secretion or action are given if surgery does not result in cure (Katznelson et al., 2014). Pituitary irradiation may be associated with significant long-term complications, including visual deterioration and pituitary dysfunction. Thus, increased attention has been given to the pharmacological management of acromegaly.

Somatostatin Analogues
The development of synthetic analogues of SST has revolutionized the medical treatment of acromegaly. The goal of treatment is to decrease GH levels to less than 2.5 ng/mL after an oral glucose tolerance test and to bring IGF-1 levels to within the normal range for age and sex. The two SST analogues used widely are octreotide and lanreotide, synthetic derivatives that have longer half-lives than SST and bind preferentially to SST₁ receptors (see Figure 42–3).

Octreotide. Octreotide exerts pharmacologic actions similar to those of SST. Octreotide (100 μg) administered subcutaneously three times daily is 100% bioactive; peak effects are seen within 30 min, serum t½ is about 90 min, and duration of action is about 12 h. An equally effective long-acting, slow-release form, octreotide LAR, is administered intramuscularly in a dose of 10, 20, or 30 mg once every 4 weeks. In addition to its effect on GH secretion, octreotide can decrease tumor size, although tumor growth generally resumes after octreotide treatment is stopped.

Lanreotide. Lanreotide autogel is a long-acting octapeptide SST analogue that causes prolonged suppression of GH secretion when administered by deep subcutaneous injection every 4 weeks. Its efficacy appears comparable to that of the long-acting formulation of octreotide. It is supplied in prefilled syringes containing 60, 90, or 120 mg.

Pasireotide. Pasireotide is a long-acting cyclohexaspeptide SST analogue that is approved for the treatment of Cushing disease (excessive cortisol production triggered by increases in ACTH release due to a pituitary adenoma; see Chapter 46) in patients who are ineligible for pituitary surgery or in whom surgery has failed. Pasireotide binds to multiple SST receptors (1, 2, 3, and 5) but has its highest affinity for the SST₁ receptor. In a head-to-head study, a greater percentage of subjects administered pasireotide LAR reached treatment goals compared to those given octreotide LAR. Pasireotide LAR also is approved for treatment of acromegaly.

Adverse Effects. Gastrointestinal side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving all three SST analogues; the incidence and severity of these side effects are similar for the three analogues. The symptoms usually diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving these drugs develop multiple tiny gallstones, presumably due
to decreased gallbladder contraction and bile secretion. Bradycardia and QT prolongation may occur in patients with underlying cardiac disease. Inhibitory effects on TSH secretion rarely lead to hypothyroidism, but thyroid function should be evaluated periodically. Pasireotide suppresses ACTH secretion in Cushing disease and may lead to a decrease in cortisol secretion and to hypocortisolism. All SST analogues decrease insulin secretion, but the simultaneous reduction in GH levels results in a reduction in insulin resistance. For octreotide and lanreotide, most patients will experience no change in glucose tolerance; however, depending on the relative effects on insulin secretion versus resistance, some patients may experience a worsening and others an improvement in glucose tolerance. Pasireotide, in addition, decreases the secretion of glucagon-like peptide 1 and glucose insulinoles peptide, two incretins that facilitate insulin secretion and inhibit glucagon secretion. As a result, glucose tolerance usually worsens significantly and antihyperglycemic therapy is often needed.

**Other Therapeutic Uses.** SST blocks not only GH secretion but also the secretion of other hormones, growth factors, and cytokines. Thus, the slow-release formulations of SST analogues have been used to treat symptoms associated with metastatic carcinoid tumors (e.g., flushing and diarrhea) and adenomas secreting VIP (e.g., watery diarrhea). Octreotide and lanreotide also can be used to treat patients who have failed surgery who have thyrotripe adenomas that oversescrete TSH. Octreotide is used for treatment of acute variceal bleeding and for perioperative prophylaxis in increased surgery. Modified forms of octreotide labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors, such as pituitary adenomas and carcinoids; modified forms labeled with β emitters such as 131I have been used in selective destruction of SST receptor-positive tumors.

**Growth Hormone Antagonists**

**Pegvisomant.** Pegvisomant is a GH antagonist approved for the treatment of acromegaly. Pegvisomant binds to the GHR but does not activate JAK-STAT signaling or stimulate IGF-1 secretion (see Figure 42–5).

The drug is administered subcutaneously as a 40-mg loading dose, followed by administration of 10 mg/d. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 30 mg/d. Pegvisomant should not be used in patients with an unexplained elevation of hepatic transaminases, and liver function tests should be monitored in all patients. In addition, lipohypertrophy has occurred at injection sites, sometimes requiring cessation of therapy; this is believed to reflect the inhibition of direct actions of GH on adipocytes. Because of concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is strongly recommended.

Pegvisomant can also be given weekly, in addition to SST analogues, when IGF-1 levels are not fully controlled by the latter drugs (Lim and Fleseriu, 2017). Pegvisomant differs structurally from native GH and is produced by recombinant DNA technology.

**Somatostatin Analogs**

In a significant number of patients with prolactinomas. At higher doses, cabergoline is used in some patients with acromegaly alone or in conjunction with SST analogues.

**Adverse Effects.** Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. Cabergoline has been linked to valvular heart disease; an effect proposed to reflect agonist activity at the serotonin SHT_2A receptor; however, this is seen primarily at the high doses used in patients being treated for Parkinson disease and is not seen in the conventionally used doses (≤2 mg/week) for patients with prolactinomas.

**Quinagolide.** Quinagolide is a nonergot D_2 receptor antagonist with a t_1/2 of about 22 h. Quinagolide is administered once daily at doses of 0.1–0.5 mg/d. It is not approved for use in the U.S. but has been used in the E.U. and Canada.

**Treatment of Growth Hormone Deficiency**

**Somatropin.** Replacement therapy is well established in GH-deficient children (Richmond and Rogol, 2010) and is gaining wider acceptance for GH-deficient adults (Molitch et al., 2011).

Humans do not respond to GH from nonprimate species. In the past, when GH for therapeutic use was purified from human cadaver pituitaries, GH was available in limited quantities and was ultimately linked to the transmission of Creutzfeldt-Jakob disease. Currently, human GH is produced by recombinant DNA technology. Somatropin refers to the many GH preparations whose sequences match that of native GH.
Pharmacokinetics. As a peptide hormone, GH is administered subcutaneously, with a bioavailability of 70%. Although the circulating $t_{1/2}$ of GH is only 20 min, its biological $t_{1/2}$ is considerably longer, and once-daily administration is sufficient.

Indications for Treatment. GH deficiency in children is a well-accepted cause of short stature. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner syndrome, Noonan syndrome, Prader-Willi syndrome, chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., $>2.25$ standard deviations below mean height for age and sex but with normal laboratory indices of GH levels). Severely affected GH-deficient adults may benefit from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short-bowel syndrome (based on the finding that GH stimulates the adaptation of GI epithelial cells). Adults considered for GH treatment should have organic etiologies for the GH deficiency and must demonstrate low GH production in response to standardized stimulation tests or have at least three other pituitary hormone deficiencies.

Contraindications. GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of active malignancy. GH replacement does not cause regrowth of pituitary tumor remnants when given to patients whose tumors have been resected. Other contraindications include proliferative retinopathy or severe nonproliferative diabetic retinopathy. In treating Prader-Willi syndrome, GH therapy must be carefully supervised. Sudden death has been observed when GH was given to children who were severely obese or who had severe respiratory impairment.

Therapeutic Uses. In GH-deficient children, somatropin typically is administered in a dose of 25–50 μg/kg/d subcutaneously in the evening; higher daily doses (e.g., 50–67 μg/kg) are employed for patients with Noonan syndrome or Turner syndrome, who have partial GH resistance. In children with overt GH deficiency, measurement of serum IGF-1 levels sometimes is used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. GH is continued until the epiphyses are fused and also may be extended into the transition period from childhood to adulthood. Children with idiopathic rather than organic GH deficiency need restaging after growth has ceased before continuing GH treatment as adults; many with this diagnosis will have normal GH levels on stimulation testing as adults.

Benefits of GH treatment in GH-deficient adults include increases in muscle mass, exercise capacity, energy, bone mineral density, and quality of life and a decrease in fat mass. For adults, a typical starting dose is 150–300 μg/d (these doses may vary depending on brand product), with higher doses used in younger patients transitioning from pediatric therapy. Either an elevated serum IGF-1 level or persistent side effects mandate a decrease in dose; conversely, the dose can be increased (typically by 100–200 μg/d) if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen inhibits GH action, women taking oral—but not transdermal—estrogen may require larger GH doses to achieve the target IGF-1 level.

Adverse Effects. In children, GH therapy is associated with remarkably few side effects. Rarely, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, or vomiting. Because of this, fuduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. The consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. Because an increased incidence of type 2 diabetes mellitus has been reported, fasting glucose levels should be followed periodically during therapy. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis.

Side effects associated with the initiation of GH therapy in adults (peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias) occur most frequently in older or obese patients and generally respond to a decrease in dose. Estrogens (e.g., birth control medications and estrogen supplements) inhibit GH action so that a larger dose is needed to maintain the same IGF-1 level. GH therapy can increase the metabolic inactivation of cortisol in the liver.

Drug Interactions. The effects of estrogen on GH therapy were noted above. This effect is much less marked with transdermal estrogen preparations. Recent studies suggested that GH therapy can increase the metabolic inactivation of glucocorticoids in the liver. Thus, GH may precipitate adrenal insufficiency in patients with occult secondary adrenal insufficiency or in patients receiving replacement doses of glucocorticoids. This has been attributed to the inhibition of the type 1 isozyme of steroid 11β-hydroxysteroid dehydrogenase, which normally converts inactive cortisone into the active 11-β-hydroxy derivative cortisol (see Chapter 46).

Insulin-like Growth Factor 1

Based on the hypothesis that GH predominantly acts via increases in IGF-1 (see Figure 42–2), IGF-1 has been developed for therapeutic use (Cohen et al., 2014). Recombinant human IGF-1 (mecasermin) and a combination of recombinant human IGF-1 with its binding protein, IGFBP-3 (mecasermin rinfabate), are FDA-approved. The latter formulation was subsequently discontinued for use in short stature due to patent issues, although it remains available for other conditions, such as severe insulin resistance, muscular dystrophy, and HIV-related adipose redistribution syndrome.

ADME. Mecasermin is administered by subcutaneous injection, and absorption is virtually complete. IGF-1 in circulation is bound by six proteins; a ternary complex that includes IGFBP-3 and the acid labile subunit accounts for more than 80% of the circulating IGF-1. This protein binding prolongs the $t_{1/2}$ of IGF-1 to about 6 h. Both the liver and kidney have been shown to metabolize IGF-1.

Therapeutic Uses. Mecasermin is FDA-approved for patients with impaired growth secondary to mutations in the GHR or postreceptor signaling pathway, patients who develop antibodies against GH that interfere with its action, and patients with IGF-1 gene defects that lead to primary IGF-1 deficiency. Typically, the starting dose is 40–80 μg/kg twice daily by subcutaneous injection, with a maximum of 120 μg/kg per dose twice daily. In patients with impaired growth secondary to GH deficiency or with idiopathic short stature, mecasermin stimulates linear growth but is less effective than conventional therapy using recombinant GH.

Adverse Effects. Side effects of mecasermin include hypoglycemia and lipohypertrophy. To diminish the frequency of hypoglycemia, mecasermin should be administered shortly before or after a meal or snack. Lymphoid tissue hyper trophy, including enlarged tonsils, also is seen and may require surgical intervention. Other adverse effects are similar to those associated with GH therapy.

Contraindications. Mecasermin should not be used for growth promotion in patients with closed epiphyses. It should not be given to patients with active or suspected neoplasia and should be stopped if evidence of neoplasia develops.

Growth Hormone–Releasing Hormone

Tesamorelin. Tesamorelin is a synthetic N-terminally modified form of human GHRH that is resistant to degradation by dipeptidyl peptidase 4 and therefore has a prolonged duration of action. Tesamorelin is able to increase the levels of GH and IGF-1, but its clinical effects are primarily to reduce visceral fat accumulation, with minimal effects on insulin resistance. Tesamorelin is FDA-approved for treatment of HIV-associated lipodystrophy but not for GH deficiency (Spoonier and Olin, 2012).
The Glycoprotein Hormones: TSH and the Gonadotropins

The gonadotropins include LH, FSH, and CG. They are referred to as the gonadotropins because of their actions on the gonads. Together with TSH, they constitute the glycoprotein family of pituitary hormones (see Table 42–2). LH and FSH were named initially based on their actions on the ovary; appreciation of their roles in male reproductive function came later. LH and FSH are synthesized and secreted by gonadotropes, which make up about 10% of the hormone-secreting cells in the anterior pituitary. LH is produced by the placenta only in primates and horses. GnRH stimulates pituitary gonadotropin production, which is further regulated by feedback effects of the gonadal hormones (Figure 42–6; see Figure 44–2 and Chapters 44 and 45). TSH is measured in the diagnosis of thyroid disorders, and recombinant TSH (thyrotropin alfa) is used in the evaluation and treatment of well-differentiated thyroid cancer (see Chapter 43).

Structure-Function Aspects of the Gonadotropins

Each gonadotropic hormone is a glycosylated heterodimer containing a common α subunit and a distinct β subunit that confers specificity of action (see Table 42–2). The heterogeneity of glycosylation on the subunits produces myriad isoforms of these hormones and may affect receptor binding and signal transduction; terminal sialate residues seem to increase plasma half-lives of these gonadotropins (Mullen et al., 2013). Among the gonadotropin β subunits, that of CG is most divergent because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues that prolong its t½. The longer t½ of hCG has some clinical relevance for its use in assisted reproduction technologies.

Physiology of the Gonadotropins

In men, LH acts on testicular Leydig cells to stimulate the de novo synthesis of androgens, primarily testosterone, from cholesterol. FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation. In women, the actions of FSH and LH are more complex. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the expression of aromatase in granulosa cells, thereby stimulating the production of estradiol. LH acts on the theca cells to stimulate the de novo synthesis of androstenedione, the major precursor of ovarian estrogens in premenopausal women (see Figure 44–1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

Regulation of Gonadotropin Synthesis and Secretion

The predominant regulator of gonadotropin synthesis and secretion is the hypothalamic peptide GnRH, a decapetide with blocked amino and carboxyl termini derived by proteolytic cleavage of a precursor peptide with 92 amino acids. Gonadotropin-releasing hormone release is pulsatile and is governed by a hypothalamic neural pulse generator (primarily in the arcuate nucleus) that controls the frequency and amplitude of GnRH release. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and downregulation of GnRH receptors on pituitary gonadotropes.

Molecular and Cellular Bases of GnRH Action

GnRH signals through a specific GPCR on gonadotropes that activates the Gs/PLC-IP3-Ca2+ pathway (see Chapter 3), resulting in increased synthesis and secretion of LH and FSH. Although cAMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenylyl cyclase activity. GnRH receptors also are present in the ovary, testis, and other sites, where their physiological significance remains to be determined.

Other Regulators of Gonadotropin Production

Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate (see Figure 42–6). The feedback effects of gonadal steroids are dependent on sex, concentration, and time. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator. Higher and more sustained levels of estradiol have positive-feedback effects that ultimately result in the gonadotropin surge that triggers ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part via its conversion by aromatase to estradiol. Gonadotropin production also is regulated by the inhibins, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibin A and B are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to inhibit FSH secretion without affecting that of LH. Inhibin A exhibits variation during the menstrual cycle, suggesting that it acts as a dynamic regulator of FSH secretion.

Molecular and Cellular Bases of Gonadotropin Action

The actions of LH and hCG on target tissues are mediated by the LH receptor; those of FSH are mediated by the FSH receptor. The FSH and LH receptors couple to Gq to activate the adenylyl cyclase–cAMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate PLC and Ca2+ signaling pathways via Gq-mediated effects on PLC. Most actions of the gonadotropins can be mimicked by cAMP analogues.
Clinical Disorders of the Hypothalamic-Pituitary-Gonadal Axis

Clinical disorders of the hypothalamic-pituitary-gonadal axis can manifest either as alterations in levels and effects of sex steroids (hyper- or hypogonadism) or as impaired reproduction. This section focuses on those conditions that specifically affect the hypothalamic-pituitary components of the axis and those for which gonadotropins are used diagnostically or therapeutically.

Deficient sex steroid production resulting from hypothalamic or pituitary defects is termed hypogonadotropic hypogonadism because circulating levels of gonadotropins are either low or undetectable. Hypogonadotropic hypogonadism in some patients results from GnRH receptor mutations; some of these mutations impair targeting of the GnRH receptor to the plasma membrane of gonadotropes, prompting efforts to develop pharmacological strategies to correct receptor trafficking and restore function (Conn et al., 2007). Many other disorders can impair gonadotropin secretion, including pituitary tumors, genetic disorders such as Kallmann syndrome, infiltrative processes such as sarcoidosis, and functional disorders such as exercise-induced amenorrhea.

In contrast, reproductive disorders caused by processes that directly impair gonadal function are termed hypergonadotropic because the impaired production of sex steroids leads to a loss of negative-feedback inhibition, thereby increasing the synthesis and secretion of gonadotropins.

- **Precocious Puberty.** Puberty normally is a sequential process requiring several years over which the GnRH neurons escape CNS inhibition and initiate pulsatile secretion of GnRH. This stimulates the secretion of gonadotropins and gonadal steroids, thus directing the development of secondary sexual characteristics appropriate for sex. Normally, the initial signs of puberty (breast development in girls and testes enlargement in boys) do not occur before age 8 in girls or age 9 in boys; the initiation of sexual maturation before this time is termed “precocious.” GnRH-dependent excessive secretion of gonadotropins is rare and causes precocious puberty in children. This condition may be due to GnRH-producing hamartomas or other CNS abnormalities, but often no specific abnormality is found. This central precocious puberty must be differentiated from that due to hormone-producing tumors of the gonads, in which case gonadotropin levels will be low. GnRH-independent precocious puberty results from peripheral production of sex steroids in a manner not driven by pituitary gonadotropins; etiologies include adrenal or gonadal tumors, activating mutations of the LH receptor in boys, and congenital adrenal hyperplasia. Synthetic GnRH analogues play important roles in the diagnosis and treatment of GnRH-dependent precocious puberty (see further discussion). In contrast, drugs that interfere with the production of sex steroids, including ketoconazole and aromatase inhibitors, are used in patients with GnRH-independent precocious puberty (Shulman et al., 2008), with varying success.

- **Sexual Infantilism.** The converse of precocious puberty is a failure to initiate the processes of pubertal development at the normal time. This can reflect defects in the GnRH neurons or gonadotropes (secondary hypogonadism) or primary dysfunction in the gonads. In either case, induction of sexual maturation using sex steroids (estrogen followed by progesterone in females, testosterone in males) is standard therapy. This suffices to direct sex differentiation in the normal manner. If fertility is the goal, then therapy with either GnRH or gonadotropins is needed to stimulate appropriate germ cell maturation.

- **Infertility.** Infertility, or a failure to conceive after 12 months of unprotected intercourse, is seen in up to 10%–15% of couples and is increasing in frequency as women choose to delay childbearing. When the infertility is due to impaired synthesis or secretion of gonadotropins (hypogonadotropic hypogonadism), various pharmacological approaches are employed. In contrast, when infertility results from intrinsic processes affecting the gonads, pharmacotherapy generally is less effective. Therapeutic approaches to male infertility are described further in this chapter; strategies for female infertility are described in Chapter 44.

### Treatment and Diagnosis of Gonadal Disorders

#### GnRH and Its Synthetic Agonist Analogues

A synthetic peptide comprising the native sequence of GnRH has been used both diagnostically and therapeutically in human reproductive disorders. In addition, a number of GnRH analogues with structural modifications have been synthesized and brought to market (Table 42-3).

*Not available in the U.S.*
GnRH Congeners
Synthetic agonist congeners of GnRH have longer half-lives than native GnRH. After a transient stimulation of gonadotropin secretion, they downregulate the GnRH receptor and inhibit gonadotropin secretion. The available GnRH agonists contain substitutions of the native sequence at position 6 that protect against proteolysis and substitutions at the carboxyl terminus that improve receptor-binding affinity. Compared to GnRH, these analogues exhibit enhanced potency and prolonged duration of action (Table 42–3).

Pharmacokinetics. The myriad formulations of GnRH agonists provide for diverse applications, including relatively short-term effects (e.g., assisted reproduction technology) and more prolonged action (e.g., depot forms that inhibit gonadotropin secretion in GnRH-dependent precocious puberty). The rates and extents of absorption thus vary considerably. The intranasal formulations have bioavailability (~4%) that is considerably lower than that of the parenteral formulations, which include products for implantation and injection (subcutaneous and intramuscular).

Clinical Uses. The depot form of the GnRH agonist leuprolide has been used diagnostically to differentiate between GnRH-dependent and GnRH-independent precocious puberty. Leuprolide depot (3.75 mg) is injected subcutaneously, and serum LH is measured 2 h later. A plasma LH level of more than 6.6 mIU/mL is diagnostic of GnRH-dependent (central) disease. Clinically, the various GnRH agonists are used to achieve pharmacological castration in disorders that respond to reduction in gonadal steroids (Fuqua, 2013). A clear indication is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a depot form of a GnRH agonist (Li et al., 2014).

Long-acting GnRH agonists are used for palliative therapy of hormone-responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (see Chapters 46 and 68). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine fibroids, acute intermittent porphyria, and priapism. They also have been evaluated off label for their potential to preserve fertility in men undergoing therapy with cytotoxic drugs for cancer treatment, although efficacy in this setting has not been established. Depot preparations can be administered subcutaneously or intramuscularly monthly or every 3 months. The long-lasting GnRH agonists have been used to avoid a premature LH surge, and thus ovulation, in various ovarian stimulation protocols for in vitro fertilization.

Adverse Effects. The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes and decreased bone density in both sexes, vaginal dryness and atrophy in women, and erectile dysfunction in men). Because of these effects, therapy in non–life-threatening diseases such as endometriosis or uterine fibroids generally is limited to 6 months. GnRH agonists are contraindicated in pregnant women.

Formulations and Indications. Leuprolide. Leuprolide is formulated in multiple doses for injection: subcutaneous (1 mg/d), subcutaneous depot (7.5 mg/month; 22.5 mg/3 months; 30 mg/4 months; 45 mg/6 months), and intramuscular depot (3.75 mg/month; 11.25 mg/3 months). It is approved for endometriosis, uterine fibroids, advanced prostate cancer, and precocious puberty. For endometriosis, leuprolide once-monthly injections (3.75 mg) or 3-month injections (11.25 mg) are also copackaged in combination with once-daily norethindrone (a steroid progestin) 5-mg tablets for oral administration. Pediatric formulations of leuprolide also are approved for central precocious puberty.

Goserelin. Goserelin is formulated as a subcutaneous implant (3.6 mg/month; 10.8 mg/12 weeks). It is approved for endometriosis, for use as an endometrial-thinning agent prior to endometrial ablation for dysfunctional uterine bleeding, and for advanced prostate and breast cancer.

Histrelin. Histrelin is formulated as a subcutaneous implant (50 mg/12 months). It is approved for central precocious puberty and advanced prostate cancer.

Nafarelin. Nafarelin is formulated as a nasal spray (200 μg/spray). It is approved for endometriosis (400 μg/d) and central precocious puberty (1600 μg/d).

Triptorelin. Triptorelin is formulated for depot intramuscular injection (3.75 mg/month; 11.25 mg/12 weeks; 22.5 mg/24 weeks) and approved for advanced prostate cancer. Buserelin and destorex are not available in the U.S.

GnRH Antagonist Analogues
Ganirelix and Cetrorelix. Ganirelix acetate and cetrorelix acetate are FDA-approved to suppress the LH surge and thus prevent premature ovulation in ovarian-stimulation protocols as part of assisted reproduction technology (see Chapter 44).

Both GnRH antagonists are formulated for subcutaneous administration. Bioavailability exceeds 90% within 1–2 h, and the t₁/₂ varies depending on the dose. Once-daily administration suffices for therapeutic effect. Hypersensitivity reactions, including anaphylaxis, have been noted in postmarketing surveillance, some with the initial dose. When used in conjunction with gonadotropin injections for assisted reproduction, the effects of estrogen withdrawal (e.g., hot flashes) are not seen. GnRH antagonists are contraindicated in pregnant women.

Cetrorelix is also used off label for endometriosis and uterine fibroids, both of which are estrogen dependent. As antagonists rather than agonists, these drugs do not transiently increase gonadotropin secretion and sex steroid biosynthesis.

Degarelix. Degarelix acetate is FDA-approved for treatment of advanced prostate cancer. Degarelix suppresses testosterone levels to 50 ng/dl or less (i.e., medical castration) and lowers prostate-specific antigen more rapidly than GnRH agonists without an initial testosterone surge (Shore, 2013).

ADME. Degarelix forms a depot gel at the site of injection and, as a consequence, is released in a biphasic pattern with a median plasma t₁/₂ of 42 days for the starting dose and 28 days for the maintenance dose. Degarelix is distributed throughout total body water, is 90% protein bound, and is degraded by proteolysis via the hepatobiliary system; degraded protein fragments are eliminated in the feces, and unmetabolized drug is eliminated via the kidneys.

Adverse Effects. Adverse effects include injection site reactions, hot flashes, weight gain, increases in transaminase and γ-glutamyltransaminase levels, prolonged QT interval, and decreased bone mineral density.

Dosage and Route of Administration. Degarelix is administered subcutaneously in the abdomen, with the site of injection varied on a regular basis. The starting dose is 240 mg administered as two injections of 120 mg on each side of the abdomen, followed by a maintenance dose of 80 mg every 28 days.

Natural and Recombinant Gonadotropins
The gonadotropins are used for both diagnosis and therapy in reproductive endocrinology. For further discussion of the uses of gonadotropins in female reproduction, see Chapter 44.

The original gonadotropin preparations for clinical therapy were prepared from human urine and included chorionic gonadotropin, obtained from the urine of pregnant women, and menotropins, obtained from the urine of postmenopausal women. Because of their relatively low purity, these gonadotropins were administered intramuscularly to decrease the incidence of hypersensitivity reactions. Subsequently, urine-derived preparations were developed with sufficient purity to be administered subcutaneously. Highly purified preparations of human gonadotropins now are prepared using recombinant DNA technology and exhibit less batch-to-batch variation. This technology is being used to produce forms of gonadotropins with increased half-lives or higher clinical efficacy. One such “designer” gonadotropin, FSH-CTP, contains the β subunit of FSH fused to the carboxy-terminal extension of hCG, thereby increasing considerably the t₁/₂ of the recombinant protein. In clinical trials, FSH-CTP has been shown to stimulate follicle maturation in vivo when injected weekly (Macklin et al., 2006).
Preparations

Follicle-Stimulating Hormone

Follicle-stimulating hormone has long been a mainstay of regimens for either ovarian stimulation or in vitro fertilization. The original menotropins formulations contained roughly equal amounts of FSH and LH, as well as a number of other urinary proteins, and were administered intramuscularly to diminish local reactions. Urofollitropin, prepared by immunonconcentration of FSH with monoclonal antibodies, is pure enough to be administered subcutaneously. The amount of LH contained in such preparations is diminished considerably.

Recombinant FSH is prepared by expressing cDNAs encoding the α and β subunits of human FSH in mammalian cell lines, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two available recombinant FSH preparations, follitropin alfa and follitropin beta, differ slightly in their carbohydrate structures: Both are more pure and exhibit less interbatch variability than do preparations purified from urine; thus, they can be administered subcutaneously. The relative advantages (i.e., efficacy, lower frequency of side effects such as ovarian hyperstimulation) of recombinant FSH versus urine-derived gonadotropins have not been definitively established (van Wely et al., 2011).

Human Chorionic Gonadotropin

The hCG used clinically originally came from the urine of pregnant women. Several urine-derived preparations are available; all of them are administered intramuscularly due to local reactions. Recombinant hCG (choriogonadotropin alfa) also is used clinically.

Recombinant Human LH

Menotropins contain considerable LH activity, thereby providing any LH activity that is needed to promote follicle maturation. Traditionally, LH was not used for ovulation induction because hCG produced identical effects via the LH receptor and had a longer t1/2. Human LH produced using recombinant DNA technology and designated lutropin alfa has been discontinued from the U.S. market but is available elsewhere.

Diagnostic Uses

Pregnancy Testing

During pregnancy, the placenta produces significant amounts of hCG, which can be detected in maternal urine. Over-the-counter pregnancy kits containing antibodies specific for the unique β subunit of hCG qualitatively assay for the presence of hCG and can detect pregnancy within a few days after a woman’s first missed menstrual period. Quantitative measurements of plasma hCG concentration by radioimmunoassay can indicate whether pregnancy is proceeding normally and can help to detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. Such assays also are used to follow the therapeutic response of malignancies that secrete hCG, such as germ cell tumors.

Timing of Ovulation

Ovulation occurs about 36 h after the onset of the LH surge. Therefore, urinary concentrations of LH, as measured with an over-the-counter radioimmunoassay kit, can be used to predict the time of ovulation. Urine LH levels are measured every 12–24 h, beginning on day 10–12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and estimate the time of ovulation. This estimate facilitates the timing of sexual intercourse to optimize the chance of achieving pregnancy.

Localization of Endocrine Disease

Measurements of plasma LH and FSH levels with β-subunit-specific radioimmunoassays are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. A plasma FSH level of 10–12 mIU/mL or greater on day 3 of the menstrual cycle is associated with reduced fertility. Elevated FSH levels also are diagnostic of menopause in women with amenorrhea in the appropriate age range.

Human CG can be used to stimulate testosterone production and thus to assess Leydig cell function in males suspected of having primary hypogonadism (e.g., in delayed puberty). A diminished response to multiple injections of hCG indicates Leydig cell failure; a normal response suggests a hypothalamic-pituitary disorder and normal Leydig cells.

Therapeutic Uses

Male Infertility

In men with impaired fertility secondary to gonadotropin deficiency (hypogonadotropic hypogonadism), gonadotropins can establish or restore fertility (Farhat et al., 2010). Treatment typically is initiated with hCG (1500–2000 IU intramuscularly or subcutaneously) three times per week until the plasma testosterone levels indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to 2000 IU twice a week or 1000 IU three times a week. If spermatogenesis does not occur with hCG alone, then recombinant FSH (typical dose of 150 IU) is added to fully induce spermatogenesis.

The most common side effect of gonadotropin therapy in males is gynecomastia, which occurs in up to a third of patients and presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for more than 6 months, and optimal spermatogenesis in some patients may require treatment for up to 2 years. Once spermatogenesis has been initiated, ongoing treatment with hCG alone usually is sufficient to support sperm production.

Cryptorchidism

Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG has been used by some to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for six doses.

Posterior Pituitary Hormones: Oxytocin and Vasopressin

The neurohypophyseal hormones oxytocin and arginine vasopressin (also called antidiuretic hormone or ADH) are cyclic nonapeptides that differ by only two amino acids (Figure 42–7). The physiology and pharmacology of vasopressin are presented in Chapter 25.
Physiology of Oxytocin

Oxytocin is synthesized as a larger precursor in neurons whose cell bodies reside in the paraventricular nucleus and, to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor peptide is rapidly cleaved to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta, but the physiologic significance of this is not known. Oxytocin acts via a specific GPCR (OXTR) closely related to the V1a and V1b vasopressin receptors. In the human myometrium, OXTR couples to Gs, activating the PLC-IP3-Ca2+ pathway and enhancing activation of voltage-sensitive Ca2+ channels, stimulating muscle contraction (Figure 42–8). Oxytocin also increases local prostaglandin production, which further stimulates uterine contraction.

Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Increases in circulating oxytocin in women in labor are difficult to detect, partly because of the pulsatile nature of oxytocin secretion and partly because of the activity of circulating oxytocinase. Nevertheless, increased oxytocin in maternal circulation is detected in the second stage of labor, likely triggered by sustained distension of the uterine cervix and vagina.

Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits its release. The inhibitory effect of relaxin appears to be the net result of a direct effect on oxytocin-producing cells and an inhibitory action mediated indirectly by endogenous opiates. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release: Ethanol inhibits release; pain, dehydration, hemorrhage, and hypovolemia stimulate release. Although peripheral actions of oxytocin appear to play no significant role in the response to dehydration, hemorrhage, or hypovolemia, oxytocin may participate in the central regulation of blood pressure. Pharmacological doses of oxytocin can inhibit free water clearance by the kidney through arginine vasopressin-like activity at vasopressin V2 receptors. As judged by the effects of intravenously administered oxytocin during labor induction, the plasma t½ of oxytocin is about 13 min.

Sites of Oxytocin Action

Uterus

During the third trimester of pregnancy, spontaneous motor activity increases progressively until the sharp rise that constitutes the initiation of labor. Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsivity to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the OXTRs.

Because of difficulties associated with the measurement of oxytocin levels and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy is debated. Exogenous oxytocin can enhance rhythmic contractions at any time, but an 8-fold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy and is accompanied by a 30-fold increase in OXTR numbers. Progesterone antagonizes the stimulatory effect of oxytocin in vitro, and refractoriness to progesterone in late pregnancy may contribute to the normal initiation of human parturition.

Breast

Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.
Brain
Studies in rodents have implicated oxytocin as an important CNS regulator of trust and of autonomic systems linked to anxiety and fear, but its importance in humans in this regard remains to be established.

Brain regions proposed to be critical in the response to fearful stimuli, including the amygdala, midbrain, and striatum, showed decreased activation in response to stressful stimuli following oxytocin treatment (Baumgartner et al., 2008; Huber et al., 2005). The role of perturbations of oxytocin signaling in mental conditions such as social phobia and autism and the possible therapeutic benefit of drugs that manipulate CNS oxytocin effects are exciting areas of ongoing investigation (Romano et al., 2016).

Clinical Use of Oxytocin
Oxytocin is used therapeutically only to induce or augment labor and to treat or prevent postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm.” In the U.S., the FDA-approved label contains this notice:

Elective induction of labor is defined as the initiation of labor in a pregnant individual who has no medical indications for induction. Since the available data are inadequate to evaluate the benefits-to-risks considerations, Pitocin is not indicated for elective induction of labor.

Induction of Labor
Induction of labor is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of pharmacological induction. Oxytocin is the drug of choice for induction of labor for women with a suitably ripened cervix (see Chapter 37 for a discussion of prostaglandins in cervical ripening). It is administered by intravenous infusion (a focus of therapy (Figure 42–8). Although tocolytic agents delay delivery in ~80% of women, they neither prevent premature births nor improve adverse fetal outcomes, such as respiratory distress syndrome. Specific tocolytic agents include β adrenergic receptor agonists, MgSO4, Ca2+ channel blockers, COX inhibitors, NO donors, and the oxytocin receptor antagonist atosiban. Atosiban is widely used in Europe but is not FDA-approved in the U.S. Chapter 44 presents additional information on tocolytic therapy.

Prevention and Treatment of Postpartum Hemorrhage
Oxytocin (10 units IM) is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, oxytocin (20 units) is diluted in 1 L of intravenous solution (yielding a concentration of 20 mU/mL) and infused at a rate of 10 mU/min until the uterus is contracted. The infusion rate then is reduced to 1–2 mU/min until the mother is ready for transfer to the postpartum unit.

Tocolytic Therapy for Established Preterm Labor
Inhibition of uterine contractions of preterm labor, or tocolysis, has been a focus of therapy (Figure 42–8). Although tocolytic agents delay delivery in ~80% of women, they neither prevent premature births nor improve adverse fetal outcomes, such as respiratory distress syndrome. Specific tocolytic agents include β adrenergic receptor agonists, MgSO4, Ca2+ channel blockers, COX inhibitors, NO donors, and the oxytocin receptor antagonist atosiban. Atosiban is widely used in Europe but is not FDA-approved in the U.S. Chapter 44 presents additional information on tocolytic therapy.

### Thyroid Hormones

Thyroid hormones are essential for normal development, especially of the CNS. In the adult, thyroid hormone maintains metabolic homeostasis and influences the functions of virtually all organ systems. Thyroid hormone contains iodine, which must be supplied by nutritional intake. The thyroid gland contains large stores of thyroid hormone in the form of thyroglobulin. These stores maintain adequate systemic concentrations of thyroid hormone despite significant variations in iodine availability and nutritional intake. The thyroidal secretion is predominantly the prohormone T₄, which is converted in the liver and other tissues to supply the plasma with the active form, T₃. Local activation of T₄ also occurs in target tissues (e.g., brain and pituitary) and is increasingly recognized as an important regulatory step in thyroid hormone action. Similarly, local deactivation of T₃ is an important regulatory step. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone TSH in a negative-feedback system. The predominant actions of thyroid hormone are mediated via nuclear TRs that modulate the transcription of specific genes.

Overt hyperthyroidism and hypothyroidism, thyroid hormone excess and deficiency, respectively, are associated with numerous clinical manifestations. Milder disease often has a subtler clinical presentation and may be identified based solely on abnormal biochemical tests of thyroid function. Maternal and neonatal hypothyroidism, due to iodine deficiency, remains a major preventable cause of mental retardation worldwide (Zimmermann, 2009). Treatment of the hypothyroid patient consists of thyroid hormone replacement (Biondi and Wartofsky, 2014). Treatments for hyperthyroidism include antithyroid drugs to decrease hormone synthesis and secretion, destruction of the gland by the administration of radioactive iodine, and surgical removal (Brent, 2008). In most patients, disorders of thyroid function can be either cured or controlled.

Likewise, thyroid malignancies are most often localized and resectable (Haugen and Sherman, 2013; Haugen et al., 2016). Metastatic disease often responds to radioiodine treatment but may become highly aggressive. Radioiodine-refractory, progressive thyroid cancers may respond to targeted chemotherapies such as tyrosine kinase inhibitors.

### Biosynthesis of Thyroid Hormones

The thyroid gland produces two fundamentally different types of hormones. The thyroid follicle produces the iodothyronine hormones T₄ and T₃. The thyroid's parafollicular cells (C cells) produce calcitonin, a peptide with 32 amino acids that is not an important endogenous hormone but can be useful as a therapeutic agent in hypercalcemia and osteoporosis (see Chapter 48). Figures 43–1 and 43–2 show the structures of the thyroid hormones and their pathways of synthesis, storage, and release.

### Chemistry of Thyroid Hormones

The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine (Figure 43–1). Following the isolation and the chemical identification of T₄, it was generally thought that all the hormonal activity of thyroid tissue could be accounted for by its content of T₄. However, careful studies revealed that crude thyroid preparations possessed greater calorogenic activity than could be accounted for by their T₄ content. The presence of a "second" thyroid hormone was debated, but T₃ was finally detected, isolated, and synthesized by Gross and Pitt-Rivers in 1952. T₃ has a much higher affinity for the nuclear TR compared with T₄ and is much more potent biologically on a molar basis. The subsequent demonstration of T₃ production from T₄ in athyreotic humans led to the practice of effective replacement in hypothyroidism with levothyroxine only.

### Biosynthesis of Thyroid Hormones

The thyroid hormones are synthesized and stored as amino acid residues of thyroglobulin, a complex glycoprotein made up of two apparently identical subunits (330 kDa each) and constituting the vast majority of the thyroid follicular colloid. The thyroid gland is unique in storing great quantities of hormone precursor in this way, and extracellular thyroglobulin is proportional to the thyroid mass. The major steps in the synthesis,
Iodine ingested in the diet reaches the circulation in the form of
storage, release, and interconversion of thyroid hormones are summarized in Figure 43–2 and described next.

**Uptake of Iodide**

Iodine ingested in the diet reaches the circulation in the form of iodide ion (I⁻). Normally, the I⁻ concentration in the blood is very low (0.2–0.4 μg/dL; ~15–30 nM). The thyroid actively transports the ion via a specific membrane-bound protein, termed the NIS (Koga and Brent, 2012; Portulano et al., 2014). As a result, the ratio of [I⁻]_intra to [I⁻]_plasma is usually between 20 and 50 and can exceed 100 when the gland is stimulated. Iodide transport is inhibited by a number of ions, such as thiocyanate and perchlorate. TSH stimulates NIS gene expression and promotes insertion of NIS protein into the membrane in a functional configuration. Thus, decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression. Iodine is accumulated by other tissues, including the salivary glands, gut, and lactating breast, and it is all mediated by a single NIS gene. Individuals with congenital NIS gene mutations have absent or defective iodine concentration in all tissues known to concentrate iodine.

**Oxidation and Iodination**

Transport of iodine from the thyroid follicular cell to the colloid is facilitated by the apical transporter pendrin. The oxidation of iodide to its active form is accomplished by thyroid peroxidase. The reaction results in the formation of MIT and DIT residues in thyroglobulin, a process referred to as organification of iodine, just prior to its extracellular storage in the lumen of the thyroid follicle.

**Formation of Thyroxine and Triiodothyronine from Iodotyrosines**

The remaining synthetic step is the coupling of two DIT residues to form T₃, or of an MIT and a DIT residue to form T₄. These oxidative reactions also are catalyzed by thyroid peroxidase. Intrafollicular and secreted T₃ are also generated by the 5'-deiodination of T₄.

**Synthesis and Secretion of Thyroid Hormones**

Because T₃ and T₄ are synthesized and stored within thyroglobulin, protolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, megalin. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. TSH enhances the degradation of thyroglobulin by increasing the activity of lysosomal thiol endopeptidases, which selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases. The liberated hormones then exit the cell. 
HORMONES AND HORMONE ANTAGONISTS

SECTION V

Figure 43–1 Thyronine, thyroid hormones, and precursors.

primarily as T₄, along with some T₃. The T₃ secreted by the thyroid derives partly from T₄ within mature thyroglobulin and partly from deiodination of T₄ (Figure 43–3), which also occurs peripherally (Figure 43–4).

Conversion of T₄ to T₃ in Peripheral Tissues

The normal daily production of T₄ is estimated to range between 80 and 100 μg; that of T₃ is between 30 and 40 μg. Although T₃ is secreted by the thyroid, metabolism of T₄ by 5', or outer ring, deiodination in the peripheral tissues accounts for about 80% of circulating T₃ (Gereben et al., 2008). In contrast, removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3',5'-triiodothyronine (rT₃; Figure 43–3). Under normal conditions, about 40% of T₃ is converted to each of T₄ and rT₃, and about 20% is metabolized via other pathways, such as glucuronidation in the liver and excretion in the bile. Normal circulating concentrations of T₃ in plasma range from 4.5 to 11 μg/dL; those of T₄ are about 1/100 of that (60–180 ng/dL). T₄ has a much higher affinity for the nuclear TR compared with T₃ and is much more potent biologically on a molar basis.

There are three iodothyronine deiodinases (Marsili et al., 2011). Types 1 and 2 (D1, D2) convert T₄ to T₃. D1 is expressed primarily in the liver and kidney and also in the thyroid and pituitary (Figure 43–4). It is upregulated in hyperthyroidism, downregulated in hypothyroidism, and inhibited by the antithyroid drug propylthiouracil. D2 is expressed primarily in the CNS (including the pituitary and hypothalamus) and brown adipose tissue, also in the thyroid, and at low levels in skeletal muscle and other tissues. The activity of D2 is unaffected by propylthiouracil. D2 localizes to the endoplasmic reticulum, which facilitates access of D2-generated T₃ to the nucleus. Organs that express D2 use the locally generated T₃ in addition to plasma T₃ and therefore may have a relatively high fractional occupancy of TRs by T₃. T₃ induces ubiquitination and degradation of the D2 enzyme. This results in suppressed levels of D2 in hyperthyroidism and elevated levels in hypothyroidism, thus helping to maintain T₃ homeostasis. D3 catalyzes inner ring or 5'-deiodination, the main inactivating pathway of T₃ metabolism; D1 performs this function to some extent. D3 is found at highest levels in the CNS and placenta and is also expressed in skin and uterus. D3 can be induced locally by inflammation and hypoxia and is highly expressed in certain tumors. Both D2 and D3 are expressed during development in time- and spatially-restricted patterns.

Figure 43–2 Major pathways of thyroid hormone biosynthesis, storage as colloid, and release.
Transport of Thyroid Hormones in the Blood

Iodine in the circulation is normally present in several forms, with 95% as organic iodine and about 5% as iodide. Most (90%–95%) organic iodine is \( T_3 \); \( T_4 \) represents a relatively minor fraction (~5%). The thyroid hormones are transported in the blood in strong but noncovalent association with several plasma proteins.

\textit{Thyroxine-binding globulin} is the major carrier of thyroid hormones. It is a glycoprotein (mass of ~63,000 Da) that binds one molecule of \( T_4 \) per molecule of protein with a very high affinity (\( K_d \approx 10^{-8} \) M); \( T_3 \) is bound less avidly. \( T_3 \) but not \( T_4 \) also is bound by \textit{trans-thyretin} (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and binds \( T_3 \) with a \( K_d \) about \( 10^{-7} \) M. Albumin also can bind \( T_4 \) when the more avid carriers are saturated, but its physiological importance is unclear. Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage (~0.03% of \( T_4 \) and ~0.3% of \( T_3 \)) of the total hormone in plasma. The differential binding affinities for serum proteins also contribute to establishing the 10- to 100-fold differences in circulating hormone concentrations and half-lives of \( T_4 \) and \( T_3 \).

Essential to understanding the regulation of thyroid function is the "free hormone" concept: Only the unbound hormone has metabolic activity. Because of the high degree of binding of thyroid hormones to plasma proteins, changes in either the concentrations of these proteins or the affinities of the hormone-protein interactions have major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 43–1).

Degradation and Excretion of Thyroid Hormones

\( T_4 \) and \( T_3 \) not only can be deiodinated but also can be metabolized by ether cleavage, conjugation, and oxidative decarboxylation (Figure 43–5). \( T_4 \) is eliminated slowly from the body, with a \( t_{1/2} \) of 6–8 days. In hyperthyroidism, the \( t_{1/2} \) is shortened to 3–4 days, whereas in hypothyroidism it may be 9–10 days. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The opposite effect is observed when binding to protein is inhibited by certain drugs (see Table 43–1). \( T_3 \), which is less avidly bound to protein, has a \( t_{1/2} \) of about 1 day.

The liver is the major site of nondeiodinative degradation of thyroid hormones; \( T_4 \) and \( T_3 \) are conjugated with glucuronic and sulfuric acids and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the

Hormones and Hormone Antagonists

Factors Regulating Thyroid Hormone Secretion

Thyrotropin is a glycoprotein hormone that consists of an α subunit, common to pituitary glycoproteins such as gonadotropins, and a unique β subunit. TSH is secreted in a pulsatile manner and in a circadian pattern (levels are slightly higher during sleep at night) that is the inverse of the cortisol circadian pattern, reflecting the fact that cortisol decreases TSH secretion. TSH secretion is controlled by the hypothalamic peptide TRH and by the concentration of free thyroid hormones in the circulation. Increased thyroid hormone inhibits transcription of both the TRH gene and the genes encoding the α and β subunits of TSH, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress. Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH. Additional mechanisms mediating the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells (Figure 43–6).

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. TRH is a tripeptide (L-tyroglutamyl-L-histidyl-L-proline amide) synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes in the anterior pituitary. The binding of TRH to its receptor, a GPCR, stimulates the G_3-PLC-IP_3-Ca^{2+} pathway and activates PKC, ultimately stimulating the synthesis of TSH. Two TRH receptors have now been identified, TRH-R1 and TRH-R2, and there are receptor-selective TRH analogues. Somatostatin, dopamine, and glucocorticoids inhibit TRH-stimulated TSH secretion.

Actions of TSH on the Thyroid

Thyroid-stimulating hormone increases the synthesis and secretion of thyroid hormone. These effects follow the binding of TSH to its receptor (a GPCR) on the plasma membrane of thyroid cells. Binding of TSH to its receptor stimulates the G_3-adenyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the G_3-PLC pathway. Multiple mutations of the TSH receptor result in clinical thyroid dysfunction.

Iodine and Thyroid Function

Adequate iodine intake is essential for normal thyroid hormone production. When iodine intake is low, thyroid hormone production is reduced, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be 10 times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting T_3. In more severe iodine deficiency, adult hypothyroidism and cretinism may occur. High levels of iodine inhibit T_3 synthesis and release. In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine. The addition of iodate to table salt (NaCl) provides a convenient iodine supplement. In the U.S., iodized salt provides 100 μg of iodine per gram. The recommended daily allowances for iodine range from 90 to 120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 290 μg for lactation (Public Health Committee of the American Thyroid Association et al., 2006). Vegetables, meat, and poultry contain minimal amounts of iodine, whereas dairy products and fish are relatively high in iodine.

Iodized Salt

Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in schoolchildren in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic. The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. The use of iodized salt is required by law in some countries, but in others, such as the U.S., the use is optional.

Transport of Thyroid Hormones Into and Out of Cells

The passage of thyroid hormones across the cell membrane is mediated by specific transporters, the most well-documented of which are two members of the SLC16A family of MCTs, MCT8 and 10 (Adjianto and Philip, 2012; van der Deure et al., 2010). MCT8 is widely expressed, including in liver, heart, and brain. MCT8 mutations cause Allan-Herndon-Dudley syndrome, characterized by neurodevelopmental defects that are likely...
due to impaired entry of $T_3$ and $T_4$ into the brain. MCT8 is also important for transport of $T_3$ out of the thyroid gland, which explains the finding of reduced serum $T_3$ concentration in patients with Allan-Herndon-Dudley syndrome (Bernal et al., 2015). MCT10 transports both $T_3$ and $T_4$ and is widely expressed, but its physiological importance for thyroid hormone transport in vivo is unknown. The organic anion transporter OATP1C1 preferentially transports $T_3$ over $T_4$ and is highly expressed in brain capillaries; in mice, OATP1C1 plays an important role in the transport of $T_3$ across the blood-brain barrier.

**Mediation of Effects by Nuclear Receptors**

Thyroid hormone action is mediated largely by the binding of $T_3$ to TRs, which are members of the nuclear receptor superfamily of transcription factors (Brent, 2012). This superfamily includes the receptors for steroid hormones, vitamin D, retinoic acid, a variety of small-molecule metabolites such as certain fatty acids and bile acids, and well as a number of "orphan receptors" (see Chapter 3).

The TRs have the classic nuclear receptor structure: an amino terminal domain, a centrally located zinc finger DNA-binding domain, and a ligand-binding domain that occupies the carboxyl terminal half of the protein. $T_3$ binds to TRs with about 10-fold greater affinity than does $T_4$, and $T_3$ is not thought to be biologically active in normal physiology. TRs bind to specific DNA sequences (thyroid hormone response elements) in the promoter/regulatory regions of target genes. The transcription of most target genes is repressed by unliganded TRs and induced in response to the binding of $T_3$. In the unliganded state, the TR ligand-binding domain interacts with a corepressor complex that includes histone deacetylases and other proteins. The binding of $T_3$ causes replacement of the corepressor complex by a coactivator complex that includes histone acetyltransferases, methyltransferases, and other proteins. Other thyroid hormone target genes, such as those encoding TRH and the TSH subunits, are negatively regulated by $T_3$. The mechanism is not well defined, but these genes tend to be induced by the unliganded TR in addition to being repressed by $T_3$.

Two genes encode TRs: THRA and THRB. THRA encodes the receptor TRα1. TRα1 is expressed in most cell types, but its major activities are in the regulation of heart rate, body temperature, skeletal muscle function, and the development of bone and small intestine. Patients with THRA mutations have oftentimes described with short stature, bony abnormalities, and chronic constipation, along with normal circulating TSH and low-normal $T_3$ levels, a syndrome termed resistance to thyroid hormone alpha (Refetoff et al., 2014; van Mullem et al., 2014).

The THRB gene has two promoters that lead to the production of TRβ1 and TRβ2. These receptors have unique amino terminal domains but otherwise are identical. TRβ1 is ubiquitous; TRβ2 has a highly restricted pattern of expression, including the pituitary and hypothalamus. TRβ1 mediates specific effects in liver metabolism (including the hypocholesterolemic effect of $T_3$); TRβ2 has roles in the negative feedback by $T_3$ on hypothalamic TRH and pituitary TSH and in the development of retinal cones and the inner ear. Mutations in THRB cause the syndrome of resistance to thyroid hormone beta. This syndrome is associated with goiter, tachycardia, impaired hearing, attention-deficit/hyperactivity disorder, and other abnormalities, and laboratory evaluation shows elevated levels of TSH, $T_4$, and $T_3$ (Refetoff, 1989).

**Nongenomic Effects of Thyroid Hormone**

Although nuclear receptors are generally thought of as DNA-binding transcription factors, nuclear receptors such as TRs also are found outside the nucleus where they can exert biological effects via rapid nongenomic mechanisms. A truncated form of TRα1 is palmitoylated and localizes to the plasma membrane, where it causes rapid $T_3$-dependent NO production as well as activation of ERK and Akt signaling (Kalyanaraman et al., 2006). Full-length TRα1 and TRβ1 reportedly associate in a $T_3$-dependent manner with the p85a subunit of PI3K, resulting in Akt activation (Hiroi et al., 2006). It is interesting to note that $T_4$ administration causes rapid vasodilation, which might be explained by the aforementioned generation of NO. There also is evidence for nongenomic actions of thyroid hormone via a plasma membrane receptor within integrin αVβ3 (Lin et al., 2011). This putative receptor binds extracellular $T_3$ in preference to $T_4$, resulting in activation of MAP kinase. The importance of nongenomic actions in thyroid hormone physiology and pathophysiology remains uncertain.

**Endogenous Thyroid Hormone–Related Compounds**

3-Iodothyronamine and thyronamine are naturally occurring decarboxylated and deiodinated analogues of thyroid hormone that do not bind to TRs (Pielh et al., 2011). These compounds can serve as ligands for the GPCR trace amine–associated receptor 1, an interaction of unknown relevance in humans.

**Major Clinical Effects of Thyroid Hormones**

**Growth and Development**

Perhaps the most dramatic example of thyroid hormone action is amphibian metamorphosis, in which the tadpole is transmogrified into a frog by the actions of $T_3$. Not only does the animal grow limbs, lungs, and other terrestrial accoutrements, but also $T_3$ causes the tail to regress.

In humans, thyroid hormone plays a critical role in brain development by mechanisms that are incompletely understood (Abduljabbar and Affifi, 2012; Mayerl et al., 2014). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation begun during the first 2 weeks of postnatal life can prevent the development of these morphological changes. The actions of thyroid hormones are not limited to the brain; most tissues are affected by the administration of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as endemic (caused by extreme iodine deficiency) or sporadic (a consequence of abnormal thyroid development or a defect in the synthesis of thyroid hormone). The affected child is dwarfed, with short extremities, mentally retardation, and listlessness. Other manifestations include puffy face, enlarged tongue, dry and doughy skin, slow heart rate, constipation, and decreased body temperature. For treatment to be fully effective, the diagnosis must be made shortly after birth and $T_3$ treatment initiated, long before these clinical manifestations are apparent. In regions of endemic iodine deficiency, iodine replacement is best instituted before pregnancy. Screening of newborn infants for deficient thyroid function is carried out in the U.S. and in most industrialized countries.

**Thermogenic Effects**

Thyroid hormone is necessary for both obligatory thermogenesis (the heat resulting from vital processes) and facultative or adaptive thermogenesis (Yehuda-Shnaidman et al., 2014). Only a few organs, including the brain, gonads, and spleen, are unresponsive to the thermogenic effects of $T_3$.

Obligatory thermogenesis is the result of $T_3$, making most biological processes thermodynamically less efficient for the sake of producing heat. It is likely that multiple mechanisms contribute to this effect, such as the induction of futile cycling and changes in mitochondrial energetics, but the specific pathways involved and their quantitative contributions have yet to be fully defined. Although the induction by $T_3$ of uncoupling protein 1 is an important thermogenic mechanism in rodent brown adipose tissue, there is no convincing evidence that induction of uncoupling proteins plays a significant role in $T_3$-induced thermogenesis in other tissues (skeletal muscle, etc.). Regardless of the mechanism, thermogenesis is highly sensitive to thyroid hormone around the physiological range. Small changes in levothyroxine replacement doses may significantly alter resting energy expenditure in the hypothyroid patient. The capacity of
T₃ to stimulate thermogenesis has evolved along with ancillary effects to support this action, such as the stimulation of appetite and lipogenesis.

**Cardiovascular Effects**

Hyperthyroid patients have tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure (Gravis and Sowers, 2014). Hyperthyroidism is a relatively common cause of atrial fibrillation. Hypothyroid patients have bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

T₃ regulates myocardial gene expression primarily through TRα1, which is expressed at a higher level in cardiomyocytes than TRβ. T₃ shortens diastolic relaxation (lusitropic effect) by inducing expression of the sarcoplasmic reticulum ATPase SERCA2 and decreasing phospholamban, a SERCA2 inhibitor. T₄ increases the force of myocardial contraction (inotropic effect) in part by inducing expression of the ryanodine channel, the calcium channel of the sarcoplasmic reticulum (see Figure 29–6). T₃ induces the gene encoding the α isoform of MHC (MHCα) and decreases expression of the MHCβ gene. Because MHCα endows the myosin holoenzyme with greater ATPase activity, this is one mechanism by which T₃ enhances the velocity of contraction. The chronotropic effect of T₇ is mediated by increases in the pacemaker ion current Iₚ in the sinoatrial node (see Chapter 30). Several proteins that comprise the Iₚ channel are induced by T₃, including HCN2 and HCN4. T₃ also appears to have a direct nongenomic vasodilating effect on vascular smooth muscle, which may contribute to the decreased systemic vascular resistance and increased cardiac output of hyperthyroidism.

**Metabolic Effects**

Thyroid hormone stimulates the expression of hepatic LDL receptors and reduces apolipoprotein B levels through non-LDL receptor pathways (Goldberg et al., 2012; Muller et al., 2014), such that hypercholesterolemia is a characteristic feature of hypothyroidism.

Thyroid hormone has complex effects on carbohydrate metabolism. Thyrotoxicosis is an insulin-resistant state. Postreceptor defects in the liver and peripheral tissues are manifested by depleted glycogen stores, enhanced gluconeogenesis, and an increase in the rate of glucose absorption from the gut. Compensatory increases in insulin secretion result in hyperinsulinemia. There may be impaired glucose tolerance or even diabetes, but the vast majority of hyperthyroid patients are euglycemic. Conversely, hypothyroidism results in decreased absorption of glucose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake. Glucose metabolism generally is not affected in a clinically significant manner in nondiabetic hypothyroid patients, although insulin requirements may decrease in the hypothyroid patient with diabetes.

**Disorders of Thyroid Function**

**Thyroid Hypofunction**

Hypothyroidism, known as myxedema when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism resulting from iodine deficiency remains a common problem. In nonendemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto thyroiditis) accounts for most cases. This disorder is characterized by circulating antibodies directed against thyroid peroxidase and, sometimes, against thyroglobulin. These conditions are examples of primary hypothyroidism, failure of the thyroid gland itself. Central hypothyroidism occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (secondary hypothyroidism) or hypothalamic failure (tertiary hypothyroidism). Hypothyroidism present at birth (congenital hypothyroidism) is an important preventable cause of mental retardation in the world (Gruters and Krude, 2012).

Common symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, mental slowness, depression, dry skin, constipation, mild weight gain, fluid retention, muscle aches and stiffness, irregular menses, and infertility. Common signs include goiter (primary hypothyroidism only), bradycardia, delayed relaxation phase of the deep tendon reflexes, cool and dry skin, hypertension, nonpitting edema, and facial puffiness. Deficiency of thyroid hormone during the first few months of life causes feeding problems, failure to thrive, constipation, and sleepiness. Retardation of mental development is irreversible if not treated promptly. Childhood hypothyroidism impairs linear growth and bone maturation. Because the signs and symptoms of hypothyroidism are nonspecific, diagnosis requires the finding of an elevated serum TSH level and reduced or low-normal serum free T₄, or in cases of central hypothyroidism, only a decreased serum free T₄.

**Thyroid Hyperfunction**

Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Increased thyroid hormone production is the most common cause, with the common link of TSH receptor stimulation and increased iodine uptake by the thyroid gland, as established by the measurement of the percentage uptake of ¹³¹I or ¹²³I in a 24-h RAIU test.

Thyroid-stimulating hormone receptor stimulation is either the result of TSH receptor stimulating antibodies in Graves disease or somatic activating TSH receptor mutations in autonomously functioning nodules or a toxic goiter. In contrast, thyroid inflammation or destruction resulting in excess “leak” of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-h RAIU test. The term subclinical hyperthyroidism is defined as those with a subnormal serum TSH and normal concentrations of free T₄ and T₃. Atrial arrhythmias, excess cardiac mortality, and excessive bone loss have been associated with this profile of thyroid function tests.

Graves disease is the most common cause of high RAIU thyrotoxicosis, accounting for 60%–90% of cases, depending on age and geographic region. Graves disease is an autoimmune disease characterized by increased thyroid hormone production, diffuse goiter, and IgG antibodies that bind to and activate the TSH receptor. As with most types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1 to 7:1. Graves disease is more common between the ages of 20 and 50 but may occur at any age. Graves disease is commonly associated with other autoimmune diseases. The characteristic exophthalmos associated with Graves disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extracellular muscles. Toxic multinodular/ multinodular goiter accounts for 10%–40% of cases of hyperthyroidism and is more common in older patients. A low RAIU value is seen in the destructive thyroiditides and in thyrotoxicosis in patients taking excessive doses of thyroid hormone.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat, increased motor activity, and increased sensitivity to catecholamines produced by the sympathetic nervous system. The skin is flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite and, if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Older patients may experience less manifestations of sympathetic nervous system stimulation and reduced symptoms compared to younger individuals, sometimes referred to as “apathetic hyperthyroidism.” Some individuals may show extensive muscular wasting as a result of thyroid myopathy. The most severe form of hyperthyroidism is thyroid storm (see section that follows on therapeutic uses of antithyroid drugs).

**Thyroid Function Tests**

Measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland; total hormone...
concentration changes with alterations in amount and affinity of TBG in plasma. Although equilibrium dialysis of undiluted serum and radioimmunoassay for FT₃ in the dialysate represent the gold standard for determining FT₃ concentrations, this assay is costly and typically unavailable in routine clinical laboratories. The most common assays used for estimating the free T₄ and free T₃ concentrations employ labeled analogues of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays are subject to influences of altered serum-binding proteins, nonthyroid disease states, acute illnesses, and other drugs. In individuals with normal pituitary function, serum measurement of TSH is the thyroid function test of choice because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones. TSH is suppressed in patients with thyrotoxicosis and elevated in those with primary hypothyroidism, and these changes generally precede abnormalities in free T₄ and free T₃.

**Therapeutic Uses of Thyroid Hormone**

The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism and for TSH suppression therapy in patients with thyroid cancer.

**Thyroid Hormone Preparations**

Synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are used for thyroid hormone therapy (Biondi and Wartofsky, 2014).

**Levothyroxine**

Levothyroxine sodium is available in tablets and liquid-filled capsules for oral administration and as a lyophilized powder for injection. Table 43–2 lists drugs and other factors that may influence levothyroxine dosage requirements. Absorption of levothyroxine occurs in the stomach and small intestine and is incomplete (~80% of the tablet dose is absorbed). Absorption is slightly increased when the hormone is taken on an empty stomach, and it is associated with less variability in TSH levels when taken this way regularly (Bach-Huynh et al., 2009). Patients with gastrointestinal problems that result in poor absorption of tablet formulations may achieve better absorption with liquid-filled capsules (Vita et al., 2014). Serum T₄ peaks 2–4 h after oral ingestion, but changes are barely discernible with once-daily dosing due to the plasma t½ of about 7 days. Given this long t½, omission of one day’s dose has only marginal effects on the serum TSH and free T₄, but to maintain consistent dosing, the patient should be instructed to take a double dose the next day. For any given serum TSH, the serum T₄/T₃ ratio is slightly higher in patients taking levothyroxine than in patients with endogenous thyroid function due to the fact that about 20% of circulating T₄ normally is supplied by direct thyroidal secretion (Gullo et al., 2011; Jonklaas et al., 2008). Follow-up blood tests typically are done about 6 weeks after any dosage change due to the 1-week plasma t½ of T₄. If patients cannot take oral medications or intestinal absorption is in question, levothyroxine may be given intravenously once daily at a dose of about 80% of the patient’s daily oral requirement.

**Thyroid Hormone Replacement Therapy in Hypothyroidism**

Thyroxine is the hormone of choice for thyroid hormone replacement therapy due to its consistent potency and prolonged duration of action (Jonklaas et al., 2014). This therapy relies on D₁ and D₂ to convert T₃ (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism (in primary hypothyroidism) or free T₃ (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism. In primary hypothyroidism, generally it is sufficient to follow TSH without free T₄. A patient with mild primary hypothyroidism will achieve a normal TSH with substantially less than a full replacement dose, but as the endogenous thyroid function declines, the dose will need to be increased. In individuals older than 60 years and those with known or suspected cardiac disease or with areas of autonomous thyroid function, institution of therapy at a subreplacement dose of L-T₄ (12.5–50 μg/d) is appropriate. The dose can be increased by 25 μg/d every 6 weeks until the TSH is normalized. The vast majority of controlled trials do not support the hypothesis that combination therapy with T₃ plus T₄ provides a better therapeutic response than does T₄ alone (Grozinsky-Glasberg et al., 2006), although for unclear reasons occasional
patients say they feel better when taking combination therapies, such as desiccated thyroid. A double-blind crossover study of hypothyroid patients comparing levotyroxine and desiccated thyroid, maintaining the same reference range TSH, found that those who preferred desiccated thyroid had lost weight on this preparation (Hoang et al., 2013). Monotherapy with levotyroxine most closely mimics normal physiology and generally is preferred (Jonklaas et al., 2014).

**Hypothyroidism During Pregnancy**

Due to the increased serum concentration of TBG induced by estrogen, the expression of D3 by the placenta, and the small amount of transplacental passage of L-T4, from mother to fetus, a higher dose of levothyroxine is usually required in pregnant patients. Overt hypothyroidism during pregnancy is associated with increased risk of miscarriage, fetal distress, preterm delivery, and impaired psychoneural and motor development in the progeny. Even mild maternal hypothyroidism may have subtle adverse effects. As part of preconception planning, the dose of levothyroxine should be adjusted to maintain the TSH in the lower portion of the reference range. Women should increase their levothyroxine dose by about 30% as soon as pregnancy is confirmed, thus anticipating the increased need (Jonklaas et al., 2014). This can be achieved by taking two extra levothyroxine tablets per week. The serum TSH is measured in the first trimester, and the levothyroxine dose is further adjusted with the goal of maintaining the TSH in the lower portion of the reference range. Subsequent dosage adjustments are based on serum TSH, measured 4–6 weeks after each adjustment. TSH should be monitored periodically through to 20 weeks’ gestation, when the dose adjustment is usually maximal, and then once between weeks 26 and 32 to confirm an adequate levothyroxine dose. The levothyroxine dose can be changed back to prepregnancy levels the day after delivery, with a follow-up TSH checked about 6 weeks later.

Isolated hypothyroxinemia during pregnancy, defined by a low serum free T4 concentration and normal serum TSH concentration, has been associated in a few studies with adverse neurocognitive development in the offspring. There are currently insufficient studies to recommend routine treatment of isolated hypothyroxinemia in pregnancy. Evaluation and treatment are further complicated by the influence of the elevated serum-binding proteins in pregnancy and lower values obtained for free T4 by the analogue method, especially in the second and third trimesters. TSH remains the best test during pregnancy to evaluate thyroid status in pregnancy and response to treatment.

**Myxedema Coma**

Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism. Common precipitating factors include infection, congestive heart failure, and medical noncompliance. Myxedema coma occurs most often in elderly patients during the winter months. Cardinal features of myxedema coma are hypothermia, respiratory depression, and decreased consciousness.

Intravenous administration of thyroid hormone is advised (Jonklaas et al., 2014). Therapy with levothyroxine is begun with a loading dose of 200–400 μg followed by a daily full replacement dose. Some clinicians recommend adding lithium (10 μg intravenously followed by 2.5 to 10 μg every 8 h) until the patient is stable and conscious. Other important aspects of therapy include ventilatory support, passive warming with blankets, correction of hyponatremia, and treatment of the precipitating cause. Treatment with intravenous glucocorticoids is recommended until coexisting adrenal insufficiency is excluded.

**Congenital Hypothyroidism**

Success in the treatment of congenital hypothyroidism depends on the age at which therapy is started and the speed with which hypothyroidism is corrected. If therapy is instituted within the first 2 weeks of life, normal physical and mental development can be achieved (Gruters and Krude, 2012; Rose et al., 2006).

To rapidly normalize the serum T4 concentration in the congenitally hypothyroid infant, an initial daily dose of levothyroxine of 10–15 μg/kg is recommended (Jonklaas et al., 2014; Leger et al., 2014). Because rapid normalization is even more important in infants with severe hypothyroidism, doses on the higher side of the range mentioned are preferred in those infants. One published study found that brand-name and generic levothyroxine were not bioequivalent in infants with severe congenital hypothyroidism (Carswell et al., 2013), and this has led some experts to recommend against generic levothyroxine in this situation (Leger et al., 2014). The goal is to achieve a free T4 in the upper half of the reference range and a TSH in the lower half, although some infants maintain a high TSH that seems to reflect mis-set feedback regulation. Laboratory evaluations of TSH and free T4 are performed 2 and 4 weeks after treatment is initiated, every 1–2 months in the first 6 months, every 2–3 months between 6 months and 3 years of age, and every 6–12 months from age 3 years until the end of growth. Monitoring should be more frequent if the results are abnormal. Soy formula may impair levothyroxine absorption, necessitating a dosage increase.

**Thyroid Hormone Replacement Therapy in Thyroid Cancer**

The mainstays of therapy for well-differentiated thyroid cancer (papillary, follicular) are surgical thyroidectomy, radiiodine (discussed in material that follows), and levothyroxine to maintain a low TSH (Haugen et al., 2016). The rationale for TSH suppression is that TSH is a growth factor for thyroid cancer, but there are no randomized controlled trials that addressed the optimal TSH target range. A reasonable approach is to adjust the levothyroxine dose to maintain a low-normal TSH value in patients without persistent disease and at low risk for recurrence (Wang et al., 2015), a mildly subnormal TSH value (~0.1 mU/L) in patients at high risk for recurrence, and a more subnormal TSH level for patients with persistent disease. The benefits of TSH suppression need to be weighed against the risks, including osteoporosis and atrial fibrillation.

**Thyroid Nodules**

Nodular thyroid disease is the most common endocrinopathy. Thyroid nodules usually are asymptomatic, although they can cause neck discomfort, dysphagia, and a choking sensation. As with other forms of thyroid disease, nodules are more frequent in women. Exposure to ionizing radiation, especially in childhood, increases the rate of nodule development. Approximately 5% of thyroid nodules that come to medical attention are malignant. Most patients with thyroid nodules are euthyroid, which should be confirmed by TSH measurement. The most useful diagnostic procedures generally are ultrasound imaging and a fine-needle aspiration biopsy. The use of levothyroxine to suppress TSH in euthyroid individuals with thyroid nodules cannot be recommended as a general practice. However, if the TSH is elevated, it is appropriate to administer levothyroxine to bring the TSH into the lower portion of the reference range.

**Adverse Effects of Thyroid Hormone**

Adverse effects of thyroid hormone generally occur only on overtreatment and are similar to the consequences of hyperthyroidism. An excess of thyroid hormone can increase the risk of atrial fibrillation, especially in the elderly, and can increase the risk of osteoporosis, especially in postmenopausal women.

**Antithyroid Drugs and Other Thyroid Inhibitors**

Myriad compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Tables 43–2 and 43–3). Several types are clinically useful:

- Antithyroid drugs, which interfere directly with the synthesis of thyroid hormones
- Ionic inhibitors, which block the iodide transport mechanism
- High concentrations of iodine, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis
- Radioactive iodine, which damages the thyroid gland with ionizing radiation

Antithyroid Drugs

The antithyroid drugs with clinical utility are the thioureylenes, which belong to the family of thioamides. Propylthiouracil is the prototype (Figure 43–7).

Mechanism of Action

Antithyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines (see Figure 43–2). These drugs are thought to inhibit the peroxidase enzyme. Inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of T\textsubscript{4} to T\textsubscript{3}. Methimazole does not have this effect; this provides a rationale for the choice of propylthiouracil over other antithyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm (Angell et al., 2015).

ADME

The antithyroid compounds currently used in the U.S. are propylthiouracil (6-\text{n-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole). In Europe, carbimazole, a carbethoxy derivative of methimazole, is available, and its antithyroid action is due to its conversion to methimazole after absorption (Figure 43–7). Pharmacological properties of propylthiouracil and methimazole are shown in Table 43–4.

Absorption of effective amounts of propylthiouracil occurs within 20–30 min of an oral dose; the duration of action is brief. The effect of a dose of 100 mg of propylthiouracil begins to wane in 2–3 h; even a 500-mg dose is completely inhibitory for only 6–8 h. As little as 0.5 mg of methimazole similarly decreases the organization of radioactive iodine in the thyroid gland, but a single dose of 10–25 mg is needed to extend the inhibition to 24 h.

The t\textsubscript{1/2} of propylthiouracil in plasma is about 75 min; that of methimazole is 4–6 h. The drugs are concentrated in the thyroid, and methimazole, derived from the metabolism of carbimazole, accumulates after carbimazole is administered. Drugs and metabolites appear largely in the urine.

Therapeutic Uses

The antithyroid drugs are used in the treatment of hyperthyroidism in the following ways:

- As definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves disease
- In conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation
- To control the disorder in preparation for surgical treatment

Methimazole is the drug of choice for Graves disease; it is effective when given as a single daily dose, has improved adherence, and is less toxic than propylthiouracil. Methimazole has a relatively long plasma and intra-thyroidal t\textsubscript{1/2}, as well as a long duration of action. The usual starting dose for methimazole is 15–40 mg per day. The usual starting dose of propylthiouracil is 100 mg every 8 h. When doses greater than 300 mg daily are

needed, further subdivision of the time of administration to every 4–6 h is occasionally helpful. Once euthyroidism is achieved, usually within 12 weeks, the dose of antithyroid drug can be reduced, but not stopped, lest an exacerbation of Graves disease occur.

Response to Treatment
The thyrotoxic state usually improves within 3–6 weeks after the initiation of antithyroid drugs. The clinical response is related to the dose of antithyroid drug, the size of the goiter, and pretreatment serum \( T_3 \) concentration. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the \( T_4 \) of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. Hypothyroidism may develop as a result of overtreatment. After treatment is initiated, patients should be examined and thyroid function tests (serum FT\(_4\) and total or free \( T_3 \) concentrations) measured every 2–4 months. Once euthyroidism is established, follow-up every 4–6 months is reasonable. Control of the hyperthyroidism is usually associated with a decrease in goiter size and normalization of serum TSH concentration. When this occurs, the dose of the antithyroid drug should be significantly decreased to avoid hypothyroidism.

Untoward Reactions
The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. Agranulocytosis is the most serious reaction, usually occurring in the first few weeks or months of therapy but sometimes later. Because agranulocytosis usually occurs rapidly and is not associated with a gradual reduction in granulocyte count, periodic prospective monitoring of granulocyte count is not generally helpful. Patients should be instructed to immediately report the development of sore throat or fever and should discontinue their antithyroid drug and obtain a granulocyte count. Agranulocytosis is reversible on discontinuation of the offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery. Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction; frequent leukocyte counts are then required.

The most common reaction is a mild urticarial papular rash that often subsides spontaneously without interrupting treatment but sometimes requires administration of an antihistamine and corticosteroids and changing to another antithyroid drug. Other less-frequent complications are pain and stiffness in the joints, pancreatitis, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of propylthiouracil. Although vasculitis was previously thought to be a rare complication, Antineutrophilic cytoplasmic antibodies (ANCA) have been reported to occur in about 50% of patients receiving propylthiouracil and rarely with methimazole.

Thyrotoxicosis in Pregnancy
Thyrotoxicosis occurs in about 0.2% of pregnancies and is caused most frequently by Graves disease. Antithyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Both propylthiouracil and methimazole cross the placenta equally, and either may be used safely in the pregnant patient. Methimazole is usually avoided in the first trimester in favor of propylthiouracil due to methimazole-associated embryopathy, and then methimazole is used for the remainder of the pregnancy due to the concern for propylthiouracil-associated liver failure in pregnancy. Carbimazole is used in the E.U. during pregnancy and is rarely associated with congenital abnormalities. The antithyroid drug dosage should be minimized to keep the serum \( FT_4 \) index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves disease often improves. Relapse or worsening of Graves disease is common after delivery, and patients should be monitored closely. Methimazole in nursing mothers, up to 20 mg daily, reportedly has no effect on thyroid function in the infant; propylthiouracil is thought to partition into breast milk even less than methimazole.

Adjuvant Therapy
Several drugs that have no intrinsic antithyroid activity are useful in the symptomatic treatment of thyrotoxicosis.

The \( \beta \) Adrenergic receptor antagonists (see Chapter 12) are effective in antagonizing the sympathoadrenergic effects of thyrotoxicosis—thereby reducing the tachycardia, tremor, and stare—and relieving palpitations, anxiety, and tension. Either propranolol, 20–40 mg four times daily, or atenolol, 50–100 mg daily, is usually given initially.

The \( Ca^{2+} \) channel blockers (diltiazem, 60–120 mg four times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias. Usually, only short-term treatment with \( \beta \) adrenergic receptor antagonists or Ca\(^{2+}\) channel blockers is required, 2–6 weeks, and it should be discontinued once the patient is euthyroid.

Immunotherapy has been used for Graves hyperthyroidism and ophthalmopathy. The B-lymphocyte-depleting agent rituximab, when used with methimazole, prolongs remission of Graves disease.

Thyroid Storm
Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem. It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and, rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis but more exaggerated. Cardinal features include fever (temperature usually >38.5°C) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore, thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Antithyroid drugs are given in large doses. Propylthiouracil is preferred over methimazole because it also impairs peripheral conversion of \( T_4 \to T_3 \). Oral iodides are used after the first dose of an antithyroid drug has been administered. Treatment of the underlying precipitating illness is essential.

Ionic Inhibitors
The ionic inhibitors are substances that interfere with the concentration of iodide by the thyroid gland. These agents are anions that resemble iodide: thiocyanate, perchlorate, and fluoroborate, all monovalent hydrated anions of a size similar to that of iodide. Thiocyanate differs from the rest qualitatively; it is not concentrated by the thyroid gland but in large amounts may inhibit the organification of iodine. Perchlorate is 10 times as active as thiocyanate. Perchlorate (ClO\(_4^-\)) blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS, and itself can be transported by NIS into the thyroid gland. The various NIS inhibitors (perchlorate, thiocyanate, and nitrate) are additive in inhibiting iodine uptake. Perchlorate can be used to control hyperthyroidism; however, when given in excessive amounts (2–3 g daily), it has caused fatal aplastic anemia. Perchlorate in doses of 750 mg daily has been used in the treatment of Graves disease, although it is not available in North America.

Perchlorate can be used to “discharge” inorganic iodide from the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active; fluoroborate (BF\(_4^-\)) is as effective as perchlorate.

Lithium decreases secretion of \( T_3 \) and \( T_4 \), which can cause overt hypothyroidism in some patients taking Li\(^+\) for the treatment of mania (see Chapter 16).

Iodine
Iodide is the oldest remedy for disorders of the thyroid gland. In high concentration, iodide can influence several of the important functions of the thyroid gland. Iodide limits its own transport and acutely and transiently inhibits the synthesis of iodothyronines and iodothyronines (the Wolff-Chaikoff effect) (Pramothin et al., 2011). An important clinical effect of high [I\(^{-}\)] plasma is inhibition of the release of thyroid hormone.
Response to Iodine in Hyperthyroidism

The response to iodine in patients with hyperthyroidism is often striking and rapid: Release of thyroid hormone into the circulation is rapidly blocked, and its synthesis is mildly decreased. In the thyroid gland, vascularity is reduced, the gland becomes much firmer, the cells become smaller, and colloid reaccumulates in the follicles as iodine concentration increases. The maximal effect occurs after 10–15 days of continuous therapy. Iodide therapy usually does not completely control the manifestations of hyperthyroidism, and the beneficial effect disappears. The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy and, in conjunction with antithyroid drugs and propranolol, in the treatment of thyrotoxic crisis.

Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident or military exposure. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30–100 mg of iodine daily will markedly decrease the thyroid uptake of radioisotopes. Strong iodine solution (Lugol solution) consists of 5% iodine and 10% potassium iodide, yielding a dose of about 8 mg of iodine per drop. KISS also is available, containing 50 mg per drop. Typical doses include 16–36 mg (2–6 drops) of Lugol solution or 50–100 mg (1–2 drops) of KISS three times a day. A potassium iodide product (Thyroshield) is available over the counter to take in the event of a radiation emergency and block the uptake of radioiodine into the thyroid gland. The adult dose is 2 mL (130 mg) every 24 h, as directed by public health officials.

Euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 43–5), and these patients do not escape from the acute Wolff-Chaikoff effect (Pramyothin et al., 2011).

### Untoward Reactions

Occasional individuals show a marked sensitivity to iodine. Angioedema is the prominent symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present; manifestations of the serum-sickness type of hypersensitivity (e.g., fever, arthralgia, lymph node enlargement, and eosinophilia) may appear. Thrombotic thrombocytopenic purpura and fatal periarteritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (iodism) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation, corza, sneezing, and irritation of the eyes with swelling of the eyelids commonly occur. Mild iodism simulates a "head cold." Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. Skin lesions are common and vary in type and intensity. Rarely, severe and sometimes-fatal eruptions (ideroma) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism and generally involute quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever, anorexia, and depression may be present. The symptoms of iodism disappear within a few days after stopping the administration of iodide. Renal excretion of I can be increased by procedures that promote Cl− excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

### Radioactive Iodine

The primary isotopes used for the diagnosis and treatment of thyroid disease are 123I and 131I. 131I is primarily a short-lived γ-emitter with a 1/2 of 13 h and is used in diagnostic studies. 123I has been used successfully with positron emission tomographic/computed tomographic scanning for more precise dosimetry in high-risk thyroid cancer (Jentzen et al., 2014). 123I has a 1/2 of 8 days and emits both γ rays and β particles. More than 99% of its radiation is expended within 56 days. 131I is used therapeutically for thyroid destruction of an overactive or enlarged thyroid and in thyroid cancer for thyroid ablation and treatment of metastatic disease.

The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, 127I. 123I is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus, the destructive β particles originate within the follicle and act almost exclusively on the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The γ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. With properly selected doses of 131I, it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues.

### Therapeutic Uses

Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. The clearest indication for radioactive iodine treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is an effective treatment when Graves disease has persisted or recurred after subtotal thyroidectomy and when prolonged treatment with antithyroid drugs has not led to remission. Finally, radioactive iodine is effective in patients with toxic nodular goiter. Sodium iodide 131I is available as a solution or in capsules containing carrier-free 131I suitable for oral administration. Sodium iodide 123I is available for scanning procedures.

### Hyperthyroidism

Radioactive iodine is a valuable alternative or adjunctive treatment of hyperthyroidism (Ross, 2011). Stable iodide (nonradioactive) may preclude treatment and imaging with radioactive iodine for weeks after the stable iodide has been discontinued. In those patients exposed to stable

---

**BRUNTON et al. 2017**

**THYROID AND ANTITHYROID DRUGS**

**CHAPTER 43**

This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient.
iodine, a 24-h radioiodine measurement of a tracer dose of $^{131}$I should be performed before $^{131}$I administration to ensure there is sufficient uptake to accomplish the desired ablation. The optimal dose of $^{131}$I, expressed amount taken up, varies in different laboratories from 80 to 150 μCi per gram of thyroid tissue. The usual total dose is 4–15 mCi with a recommended target of delivering 8 mCi to the thyroid gland based on the 24-h radioiodine uptake (Alexander and Larsen, 2002; Brent, 2008).

Beginning a few weeks after treatment, the symptoms of hypothyroidism gradually abate over a period of 2–3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6–12 months. It is not uncommon, however, for the serum TSH to remain low for several months after $^{131}$I therapy. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free T₄ and usually serum T₃ concentrations. Depending to some extent on the dosage schedule adopted, 80% of patients are cured by a single dose, about 20% require two doses, and a very small fraction require three or more doses before the disorder is controlled. β-Adrenergic antagonists, antithyroid drugs, or both can be used to hasten the control of hyperthyroidism.

Advantages

With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the U.S., and patients can participate in their customary activities during the entire procedure, although there are recommendations to limit exposure in young children.

Disadvantages

The chief consequence of the use of radioactive iodine is the high incidence of delayed hypothyroidism. Although cancer death rate is not increased after radiiodine therapy, some studies suggest a small but significant increase in specific types of cancer, including stomach, kidney, and breast. This finding is especially significant because these tissues all express the iodine transporter NIS and may thus be especially susceptible to effects of radioactive iodine. Radioactive iodine treatment can induce a radiation thyroiditis, with release of preformed T₃ and T₄ into the circulation. In most patients, this is asymptomatic, but in some there can be worsening of symptoms of hyperthyroidism; rarely, cardiac manifestations (e.g., atrial fibrillation or ischemic heart disease); and very rarely thyroid storm. Pretreatment with antithyroid drugs should reduce or eliminate this complication.

The main contraindication for the use of $^{131}$I therapy is pregnancy. After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. In addition, the use of radioiodine to treat hyperthyroidism in children is controversial due to theoretical concern about causing neoplastic changes in the thyroid gland or other organs. Data are insufficient to resolve this issue, as the number of children who have been treated with radioiodine is relatively small. Many clinics decline to treat younger patients and reserve radioactive iodine for patients older than 25–30 years.

Thyroid Carcinoma

Because most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH is required to treat metastases effectively (Haugen and Sherman, 2013; Haugen et al., 2016). Endogenous TSH stimulation is promoted by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total or total thyroidectomy. An ablative dose of $^{131}$I ranging from 30 to 150 mCi is administered, and a repeat total body scan is obtained several days to 1 week later.

Recombinant thyrotropin alpha (recombinant human TSH) can be used instead of thyroid hormone withdrawal to prepare a patient for radioiodine ablation of thyroid remnant tissue or to test the capacity of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin. Recombinant human TSH is not currently approved to prepare patients for radioiodine ablation of metastatic disease.

Chemotherapy of Thyroid Cancer

Papillary and Follicular Carcinomas

The majority of thyroid cancers derive from the thyroid follicular cells and are classified histologically as papillary or follicular carcinomas. Most of these carcinomas are adequately treated by surgery, radioiodine, and levothyroxine to suppress TSH. However, a small fraction progress despite these therapies, in which case they can be treated with the oral tyrosine kinase inhibitors sorafenib (Brose et al., 2014) or lenvatinib (Schlumberger et al., 2015) (see Chapter 67). The response to these drugs does not seem to be dependent on the presence or absence of specific oncogene mutations.

The recommended daily dose of sorafenib is 400 mg twice daily without food. Adverse reactions include palmar-plantar erythrodysesthesia, diarrhea, alopecia, fatigue, weight loss, hypertension, and others. The recommended daily dose of lenvatinib is 24 mg once daily with or without food, reduced to 14 mg in those with severe renal or hepatic impairment. Common adverse reactions include hypertension, diarrhea, fatigue, decreased appetite, decreased weight, nausea, stomatitis, and musculoskeletal pain, although there are multiple other toxicities, including treatment-related deaths.

Medullary Thyroid Carcinoma

A minor fraction of thyroid cancers originate from the parafollicular cells (C cells) that produce calcitonin and are denoted medullary thyroid carcinomas. Because they derive from the parafollicular cells, medullary carcinomas are not responsive to radioiodine or TSH suppression. Medullary carcinomas that progress despite surgery can be treated with either of the oral tyrosine kinase inhibitors vandetanib (Wells et al., 2012) and cabozantinib (Elisei et al., 2013) (see Chapter 67). These drugs can be prescribed for both the sporadic and inherited forms of medullary thyroid carcinoma without regard for RET gene mutational status because patients can respond even in the absence of RET mutations. However, the phase III vandetanib trial suggested a higher response rate in patients with tumors harboring the RET M918T mutation. The phase III cabozantinib trial demonstrated a longer progression-free survival in patients with RET M918T tumors and possibly also in patients with tumors harboring RAS mutations.

The dose of vandetanib is 300 mg once daily with or without food. The dose is reduced to 200 mg in moderate-to-severe renal impairment, and vandetanib is not recommended in moderate or severe hepatic impairment. Vandetanib has a black-box warning for QT prolongation. Additional adverse reactions include diarrhea, rash, nausea, hypertension, headache, and others.

The starting dose of cabozantinib is typically 60–100 mg on an empty stomach, which may be titrated to 140 mg as tolerated. It is not recommended in moderate or severe hepatic impairment. Cabozantinib has black-box warnings for GI perforations and fistulas (especially in patients receiving prior radiation therapy) and hemorrhage. Additional adverse reactions include diarrhea, palmar-plantar erythrodysesthesia, decreased weight and appetite, nausea, fatigue, and stomatitis.

General Comments

Treatment of thyroid cancer with tyrosine kinase inhibitors should continue until the patient is no longer clinically benefiting or until unacceptable toxicity occurs. Dosage reductions can mitigate toxicity. Resistance to one tyrosine kinase inhibitor does not necessarily imply resistance to another. It is important to note that levothyroxine dosage requirements often increase in patients taking protein tyrosine kinase inhibitors; therefore, TSH levels should be monitored carefully (Brose et al., 2014; Elisei et al., 2013; Schlumberger et al., 2015; Wells et al., 2012). The use of tyrosine kinase inhibitors is described in Chapter 67.

  • Congenital hypothyroidism requires rapid diagnosis and correction to allow normal physical and mental development  
  • Overtreatment can lead to osteoporosis and atrial fibrillation |
| Liothyronine (T₃) | • When rapid onset of action is desired (sometimes for myxedema coma)  
  • When rapid termination of action is desired (preparing patients with thyroid cancer for radioiodine therapy) | • Plasma t½ ~ 18-24 h  
  • Multiple daily doses needed to achieve needed C₃ₙs  
  • Levothyroxine (T₄) generally preferred over liothyronine (T₃) for the long-term therapy of hypothyroidism |
| Desiccated thyroid and T₄-T₃ mixtures | • Generally not a preferred therapy, although occasional hypothyroid patients say they feel better than when taking levothyroxine | • Mixture of levothyroxine and liothyronine (2–5:1 by weight)  
  • Supplies a relative excess of T₃ compared to normal thyroidal secretion, which is ~ 11:3 T₄ to T₃ by weight  
  • No convincing evidence of greater efficacy than levothyroxine (T₄ alone) |
| **Antithyroid Drugs: Thionamides: Interfere with incorporation of iodine into tyrosyl residues and inhibit iodothyrosyl-coupling reactions** |
| Methimazole | • Reduce thyroid hormone production | • Carbimazole (available in Europe) converted to methimazole after absorption  
  • Long intrathyroidal t½ allows once-daily dosing for most patients  
  • Preferred antithyroid drug  
  • Do not use in first trimester of pregnancy due to embryopathy |
| Propylthiouracil | • Reduce thyroid hormone production  
  • May also reduce T₄ to T₃ conversion | • Major concern is liver toxicity; rare but more commonly seen in children and pregnancy  
  • Only indications are for thyroid storm due to action on reducing T₄ to T₃ conversion and in the first trimester of pregnancy |
| **Antithyroid Drugs: Iodic Inhibitors: Iodine uptake by antagonizing the sodium-iodide symporter** |
| Perchlorate | • Primarily used to enhance the response to thiouramides in refractory Graves disease (e.g., that associated with amiodarone) | • Not available commercially; must be specialty compounded |
| **Antithyroid Drugs: Iodide: Acute reduction in thyroid hormone** |
| Lugol solution | • Acutely reduce the secretion and synthesis of thyroid hormone | • “Escape” from thyroid inhibition after 7–10 days  
  • Strictly contraindicated in pregnancy |
| KISS: potassium iodide saturated solution (or SSKI) | • Acutely reduce the secretion and synthesis of thyroid hormone | • “Escape” from thyroid inhibition after 7–10 days  
  • Strictly contraindicated in pregnancy |
| **Antithyroid Drugs: Radioactive Iodine: Used to destroy hyperfunctioning thyroid tissue** |
| ¹³¹I | • Effective for permanent treatment of Graves disease and toxic nodules or toxic goiter  
  • Destruction of iodide-avid thyroid cancer | • Highly effective for permanent cure to hyperthyroidism  
  • Effective treatment of hyperthyroidism usually results in permanent hypothyroidism and lifelong requirement for levothyroxine replacement  
  • Absolutely contraindicated in pregnancy  
  • Treatment of thyroid cancer requires TSH stimulation (endogenous or exogenous) |
| **Recombinant Human TSH Agonist for the TSH Receptor** |
| Thyrotropin alpha | • Stimulate radioiodine uptake and thyroglobulin release in patients with thyroid cancer after thyroidectomy  
  • Prepare patients for radioiodine ablation of thyroid remnants after thyroidectomy for thyroid cancer | • Allows assessment of residual or recurrent thyroid cancer without stopping levothyroxine and becoming clinically hypothyroid  
  • Allows radioiodine therapy of thyroid remnants without stopping levothyroxine and becoming clinically hypothyroid |
| **Thyroid Cancer Chemotherapeutics: Tyrosine kinase inhibitors** |
| Sorafenib | • Radioiodine-resistant, progressive papillary, or follicular thyroid cancer | • Response not predicted by presence or absence of specific oncogene mutations  
  • Lack of response to one kinase inhibitor does not necessarily predict lack of response to others |
| Lenvatinib | | |
| Vandetanib | • Progressive medullary thyroid cancer | • Can be used in hereditary or sporadic medullary thyroid cancer  
  • Responses may be seen in patients with or without RET gene mutations |

Estrogens and progestins are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. Well-characterized receptors for each hormone mediate biological actions in both the unliganded and the liganded states.

The most common uses of estrogens and progestins are for contraception and menopausal hormone therapy (MHT) in women, but the specific compounds and dosages used in these two settings differ substantially. Antiestrogens are used in the treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are useful to prevent breast cancer and osteoporosis. The main use of antiprogestins has been for medical abortion.

A number of naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown but is an area of active investigation.

Estrogens

Chemistry and Synthesis

Chemistry
Many steroidal and nonsteroidal compounds, some of which are shown in Table 44–1 and Figure 44–1, possess estrogenic activity. Estrogens interact with two receptors of the nuclear receptor superfamily, termed ERα and ERβ. The most potent naturally occurring estrogen in humans, for both ERα- and ERβ-mediated actions, is 17β-estradiol, followed by estrone and estriol. Each contains a phenolic A ring with a hydroxyl group at carbon 3 and a β-OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethinyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both ERs have been determined from structure-activity relationships and structural analysis (Pike et al., 2000). Selective ligands for ERα and ERβ are available for experimental studies but are not yet used therapeutically (Harrington et al., 2003).

Biosynthesis
Steroidal estrogens arise from androstenedione or testosterone (Figure 44–1) by aromatization of the A ring. The reaction is catalyzed by aromatase (CYP19), which uses NADPH and molecular oxygen as cosubstrates. A ubiquitous flavoprotein, NADPH–cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson et al., 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol the main secretory product. Ovarian estradiol production is traditionally thought to require two cell types: theca cells and granulosa cells. The gonadotropin LH acts via receptors that couple to the Gs-adenyl cyclase–cyclic AMP pathway to increase
cholesterol (the precursors of all steroids) transport into the mitochondria of cells, where androgen precursors are produced. FSH then stimulates CYP19 production and activity in the granulosa cells, which converts the androgen precursors to estrogens. Notably, theca cells of the ovary contain a form of 17β-hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo et al., 1999), and both of these steroids are then converted to estritol (Figure 44–1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

Abbreviations

AF: activation function
CHD: coronary heart disease
COMT: catechol-O-methyl transferase
DES: diethylstilbestrol
ER: estrogen receptor
ERα: estrogen receptor α
ERβ: estrogen receptor β
ERE: estrogen response element
ERT: estrogen replacement therapy
FP: PGF 2α receptor
FSH: follicle-stimulating hormone
GABA: γ-aminobutyric acid
GnRH: gonadotropin-releasing hormone
GPCR: G protein–coupled receptor
hCG: human chorionic gonadotropin
HDL: high-density lipoprotein
HERS: Women’s Health Initiative Memory Study
HER2: estrogen receptor β
HER3: estrogen receptor α
HRT: hormone replacement therapy
HSP: heat shock protein
IGF: insulin-like growth factor
IU: intrauterine
IUD: intrauterine device
IUH: intrauterine insemination
IUS: intrauterine system
LDL: low-density lipoprotein
LH: luteinizing hormone
LNG: levonorgestrel, as in LNG-IUS
LNG14 or 20: LNG 14 or 20 μg/24h
LPA: lipoprotein A
MHT: menopausal hormone therapy
MPA: medroxyprogesterone acetate
MWS: Million Women Study
NcoR: nuclear hormone receptor corepressor
NE: norepinephrine
OHSS: ovarian hyperstimulation syndrome
PAI-1: plasminogen activator inhibitor 1
PCOS: polycystic ovary syndrome
PG: prostaglandin
PID: pelvic inflammatory disease
PR: progesterone receptor
PRE: progesterone response element
PRM: progesterone receptor modulator
ROS: reactive oxygen species
SERM: selective estrogen receptor modulator
SHBG: sex hormone–binding globulin
SRC-1: steroid–receptor coactivator 1
WHI: Women’s Health Initiative
WHIMS: Women’s Health Initiative Memory Study

HISTORY

Hormones in the Female Reproductive System

The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based on the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance.

Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s. In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamilly and provided techniques to identify receptors for the other steroid hormones. A second ER was identified in 1996 and was termed ERβ to distinguish it from the receptor identified by Jensen and others, termed ERα. Two protein isoforms, A and B, of the PR arise from a single gene by transcription initiation from different promoters.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrogen is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens (Simpson, 2003).

Estrogens may be locally produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal or promotional role in the development of certain diseases, such as breast cancer, because mammary tumors contain both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens via aromatase in the CNS and other tissues and exert local effects near their production site (e.g., in bone, they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16α-hydroxyl derivative to produce large amounts of estrone and estriol. Human urine during pregnancy is thus an abundant source of natural estrogens. Pregnant mare’s urine is the source of conjugated equine estrogens, which have been widely used therapeutically for many years.

Physiological Actions

Developmental Actions

Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. Estrogens cause growth and development of the vagina, uterus, and fallopian tubes and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areola that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (Chapter 45).

Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays...

skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

**Neuroendocrine Control of the Menstrual Cycle**

A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 44–2). A neuronal oscillator, or “clock,” in the hypothalamus fires at intervals that coincide with bursts of GnRH release into the hypothalamic-pituitary portal vasculature (Chapter 42). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of LH and FSH. The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle, controls the relative synthesis of the unique β subunits of FSH and LH.

The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovarian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus. Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse frequency is determined by the neural clock (Figure 44–2), termed the hypothalamic GnRH pulse generator (Knobil, 1981), but the amount of gonadotropin released in each pulse (i.e., the pulse amplitude) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, pulsatile nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles because constant infusion of GnRH results in cessation of gonadotropin release and ovarian steroid production (Chapter 42). The neuropeptide kisspeptin 1, which is released from the hypothalamic anteroventral periventricular nucleus and the arcuate nucleus, may regulate GnRH pulsatility through its G protein–coupled receptor, GPR54, expressed in GnRH neurons. Inactivating mutations in GPR54 have been associated with hypogonadotropic hypogonadism (Seminara, 2006).

Although the precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, hypothalamic cells appear to have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, and GABAergic neurons (Figure 44–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established.

At puberty the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. Although the mechanism of activation is not entirely established, it may involve increases in circulating IGF-1.
and leptin levels, the latter acting to inhibit neuropeptide Y in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 44–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The "average" plasma levels of LH throughout the cycle are shown in panel A of Figure 44–3; inserts illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive- and negative-feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle, (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that correspond with pulses of GnRH secretion; (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes; and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline (i.e., the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall (Figure 44–3). Inhibin, produced by the ovary, exerts negative feedback to selectively decrease serum FSH (Chapter 42). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At midcycle, serum estradiol rises above a threshold level of 150–200 pg/mL for about 36 h. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive-feedback effect on the

**Figure 44–3** Hormonal relationships of the human menstrual cycle. A. Average daily values of LH, FSH, estradiol (E₂), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (top) and endometrium (bottom) also are illustrated schematically. Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Modified from and reproduced with permission from Thorneycroft IH, et al. *Am J Obstet Gynecol*, 1971, 111:947–951. Copyright © Elsevier). B. Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of FSH and LH released (i.e., gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at midcycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (i.e., the pulse amplitude) during the luteal phase of the cycle.
pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. Progesterone may contribute to the midcycle LH surge.

The midcycle surge in gonadotropins stimulates follicular rupture and ovulation within 1–2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and they may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release but then have a brief midcycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing PRs) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle and less-frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicated that ERα (Hewitt and Korach, 2003) and PR-A (Conneely et al., 2002) mediate the major actions of estrogens and progesterins, respectively, on the hypothalamic-pituitary axis.

When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen.

Effects of Cyclical Gonadal Steroids on the Reproductive Tract

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an endometrium and a myometrium. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers, the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 44–3).

The luminal surface of the endometrium is a layer of simple columnar epithelial secretory and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The endometrial stroma is a highly cellular connective tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. An important response to estrogen in the endometrium and other tissues is induction of the PR, which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely et al., 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow “window of implantation,” spanning days 19–24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. If implantation occurs, hCG (Chapter 42), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. Later, the placenta becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, and progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

Metabolic Effects

Estrogens affect many tissues and have many metabolic actions in humans and animals. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, GI tract, and heart, express low levels of both ERs, and the ratio of ERα to ERβ varies in a cell-specific manner. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

Estrogens have positive effects on bone mass (Riggs et al., 2002). Bone is continuously remodeled at sites called bone-remodeling units by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (Chapter 48). Estrogens directly regulate osteoblasts and increase osteocyte survival by inhibiting apoptosis (Kousteni et al., 2002; Levin, 2008). However, a major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both para- and autocrine) signals from osteoblasts. Estrogens also increase osteoblast production of the cytokine osteoprotegerin (OPG), a soluble, non–membrane-bound member of the tumor necrosis factor superfamily. OPG acts as a “decoy” receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed RANK, or receptor activator of NF-κB) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith et al., 1994).

Estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. They increase HDL levels and decrease the levels of LDL and LPA (Chapter 33). This beneficial alteration of the ratio of HDL to LDL is an attractive but unproven effect of estrogen therapy in postmenopausal women. At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Estrogens actions on the
vascular wall include increased production of NO, which occurs within minutes via a mechanism involving activation of Akt (protein kinase B) and induction of NO synthase (Simionescu et al., 2000). All of these changes promote vasodilation and retard atherosclerosis. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

The presence of ERs in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroid hormone-binding globulin, and SHBG, which binds both androgens and estrogens.

Estrogens alter a number of metabolic pathways that affect the clotting cascade (Mendelsohn and Karas, 1999). Systemic effects include changes in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and they decrease the anticoagulation factors protein C, protein S, and antithrombin III (Chapter 32). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of PAI-1 protein with a concomitant increase in fibrinolysis (Koh et al., 1997). Thus, estrogens increase both coagulation and fibrinolytic pathways, and imbalance in these two opposing activities may cause adverse effects.

**Estrogen Receptors**

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two ER genes are located on separate chromosomes: \( ESR1 \) encodes ERα, and \( ESR2 \) encodes ERβ. Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ERα and ERβ exist as multiple mRNA isoforms due to different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004).

**Mechanism of Action**

Both ERs are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 44–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to HSP90, and on binding estrogen, a change in ER conformation dissociates the HSPs and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskis et al., 1997). Homodimers of ERα or ERβ and ERα/ERβ heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER, ERα, and ERβ contains two receptor isoforms in the ligand-binding domains and in both transactivation domains. Human ERβ does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper et al., 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

**Estrogen receptor a** is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. ERβ is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both ERα and ERβ, which can form either homo- or heterodimers. Both forms of ER are expressed on breast cancers, although ERα is believed to be the predominant form responsible for growth regulation (Chapter 67). When coexpressed with ERα, ERβ can inhibit ERα receptor-mediated transcriptional activation in many cases (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han et al., 2003), bone mass (Kurabayashi et al., 2004), endometrial cancer (Weiderpass et al., 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

A cloned G protein–coupled receptor, GPR30, also appears to interact with estrogens in some cell systems, and its participation in the rapid effects of estrogen is an attractive idea. There may be interaction/cross-talk between membrane-associated ERα and membrane-localized GPR30 in some cancer cells, but in vivo confirmation is lacking (Levin, 2008; Old and Leeb-Lundberg, 2009).
 Estradiol is available in nonmicro-
ized and micronized preparations. The micronized formulations yield a large surface for rapid absorption to partially overcome low absolute oral bioavailability due to first-pass metabolism (Fotherby, 1996). Addition of the ethinyl substituent at C17 (ethinyl estradiol) inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens, which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; esterified esters, or mixtures of synthetic conjugated estrogens prepared from plant-derived sources. These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, estropipate, estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, for example, is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 44–1), which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials ( Fitzpatrick, 2003).

Administration of estradiol via transdermal patches provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical emulsion applied to the upper thigh and calf or as a gel applied once daily to the arm. The transdermal route does not lead to the high levels of the drug that occur in the portal circulation after oral administration, and it is thus expected to minimize hepatic effects of estrogens (e.g., effects on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

When dissolved in oil and injected, esters of estradiol are well absorbed. Preparations available for intramuscular injection include compounds such as estradiol valerate or estradiol cypionate and may be absorbed over several weeks following a single intramuscular injection.

Preparations of estradiol and conjugated estrogen creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring may be used for slow release of estradiol, and tablets are also available for vaginal use ( Vagifem).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend on the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms ( Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma t ½ measured in minutes. Estradiol is converted primarily by 17β-hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16α-hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in

Figure 44–4 Molecular mechanism of action of nuclear ER. A. Unliganded ER exists as a monomer within the nucleus. B. Agonists such as 17β-estradiol (E) bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific ERE sequences in DNA. The ER-DNA complex recruits coactivators such as SWI/SNF that modify chromatin structure and coactivators such as SRC-1 that has histone acetyltransferase activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other coactivators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. C. Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced conformation also facilitates dimerization and interaction with DNA, but a different set of proteins called corepressors, such as NcoR, are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histones to stabilize nucleosome structure and prevent interaction with the GTA.
Selective Estrogen Receptor Modulators and Antiestrogens

By altering the conformation of the two different ERs and thereby changing interactions with coactivators and corepressors in cell-specific and promoter-specific contexts, ligands may have a broad spectrum of activities from purely antiestrogenic in all tissues, to partially estrogenic in some tissues with antiestrogenic or no activities in others, to purely estrogenic activities in all tissues. The elucidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with selective patterns of estrogenic activity (Smith and O’Malley, 2004).

Selective Estrogen Receptor Modulators: Tamoxifen, Raloxifene, and Toremifene

Selective ER modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) during post-MHT but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (e.g., carcinogenesis) might be deleterious. Currently approved drugs in the U.S. in this class are tamoxifen citrate, raloxifene hydrochloride, and toremifene, which is chemically related and has similar actions to tamoxifen. Toremifene and toremifene are used for the treatment of breast cancer, and raloxifene is used primarily for the prevention and treatment of osteoporosis and to reduce the risk of invasive breast cancer in high-risk postmenopausal women. They are considered in detail in Chapter 68.

Antiestrogens: Clomiphene and Fulvestrant

The antiestrogen compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene is approved for the treatment of infertility in anovulatory women, and fulvestrant is used for the treatment of breast cancer in women with disease progression after tamoxifen.

Chemistry

The structures of the trans-isomer of tamoxifen, of raloxifene, trans-clomiphene (enclomiphene), and fulvestrant are as follows:

Tamoxifen is a triphenylethylene with the same stilbene nucleus as DES; compounds of this class display a variety of estrogenic and antiestrogenic activities. In general, the trans conformations have antiestrogenic activity, whereas the cis conformations display estrogenic activity. However, the pharmacological activity of the trans compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily N-desmethyltamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active 4-hydroxy metabolite, which has a 25–50 times higher affinity for both ERα and ERβ than does tamoxifen (Kuiper et al., 1997). Tamoxifen is marketed as the pure trans-isomer. Toremifene is a triphenylethylene with a chloride substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiophene core. Raloxifene binds with high affinity for both ERα and ERβ (Kuiper et al., 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, zuclocliphene (cis clomiphene) and enclomiphene (trans clomiphene), are weak estrogen agonist and a potent antagonist, respectively. Clomiphene binds to both ERα and ERβ, but the individual isomers have not been examined (Kuiper et al., 1997).

Fulvestrant is a 7α-alkylamide derivative of estradiol that interacts with both ERα and ERβ (Van Den Bernd et al., 1999).

Pharmacological Effects

All of these agents bind to the ligand-binding pocket of both ERα and ERβ and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O’Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different coactivators and corepressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different coactivator and corepressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.
Tamoxifen. Tamoxifen exhibits antiestrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug’s activity depends on the tissue and end point measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (Jaiyesimi et al., 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti et al., 1993). The drug has an antiresorptive effect on bone, and in humans it decreases total cholesterol, LDL, and LPA but does not increase HDL and triglycerides (Love et al., 1994). Tamoxifen treatment causes a 2- to 3-fold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly 2-fold increase in endometrial carcinoma (Smith, 2003). Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.

The conformation of ERs, especially in the AF-2 domain, determines whether a coactivator or a corepressor will be recruited to the ER-DNA complex (Smith and O'Malley, 2004). Tamoxifen induces a conformation that permits the recruitment of the corepressor to both ERα and ERβ, in contrast to 17α-estradiol, which induces a conformation that recruits coactivators to the receptor. The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ERα; because ERβ does not contain a functional AF-1 domain, tamoxifen does not activate ERβ (McInerney et al., 1998).

Raloxifene. Raloxifene is an estrogen agonist in bone, where it exerts an antiresorptive effect. The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize PAI-1 in postmenopausal women (Walsh et al., 1998). Studies indicated that raloxifene has an antiproliferative effect on ER-positive breast tumors and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings et al., 1999). Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a 3-fold increase in deep vein thrombosis and pulmonary embolism (Cummings et al., 1999).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression of transcription factors in the two tissues and the effects of this SERM on ER conformation. Raloxifene induces a configuration in ERα that is distinct from that of tamoxifen-ERβ (Tamrazi et al., 2003), suggesting that a different set of coactivators/corepressors may interact with ER-raloxifene compared with ER-tamoxifen.

Fulvestrant. Fulvestrant is antiestrogenic. In clinical trials, it is efficacious in treating tamoxifen-resistant breast cancers (Robertson et al., 2003). Fulvestrant binds to ERα and ERβ with high affinity comparable to estradiol but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ERα while apparently protecting ERβ from degradation (Van Der Bemd et al., 1999). This effect on ERα protein levels may explain fulvestrant’s efficacy in tamoxifen-resistant breast cancer.

Clomiphene. Clomiphene increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel et al., 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

The most prominent effect of clomiphene in women was enlargement of the ovaries and the drug-induced ovulation in many patients with amenorrhea, polycystic ovarian syndrome, and dysfunctional bleeding with anovulatory cycles. Thus, clomiphene’s major pharmacological use is to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, clomiphene is used in conjunction with human gonadotropins (Chapter 42) to induce ovulation.

ADME

Tamoxifen is given orally, and peak plasma levels are reached within 4–7 h. It has two elimination phases with half-lives of 7–14 h and 4–11 days. Due to the prolonged $t_{1/2}$, 3–4 weeks of treatment are required to reach steady-state plasma levels. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridhar et al., 2002). In humans and other species, 4-hydroxytamoxifen is produced via hepatic metabolism, and this compound is considerably more potent than the parent drug as an antiestrogen. The major route of elimination from the body involves N-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite. Polymorphisms affect the rate of tamoxifen metabolism to its more potent 4-hydroxy metabolite and may affect its therapeutic activity in breast cancer (Chapter 67).

Fulvestrant is absorbed rapidly after oral administration and has an absolute bioavailability of about 2%. The drug has a $t_{1/2}$ of about 28 h and is eliminated primarily in the feces after hepatic glucuronidation.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma $t_{1/2}$ (5–7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissue.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed in vivo, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) via the feces in humans.

Therapeutic Uses

Breast Cancer. Tamoxifen is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiyesimi et al., 1995). Response rates are about 50% in women with ER-positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. Tamoxifen reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years because effectiveness decreases thereafter. The most frequent side effect is hot flashes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by 2- to 3-fold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy (Smith, 2003) and women with a history of deep vein thrombosis or stroke.

Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

Osteoporosis. Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, raloxifene increased spinal bone mineral density by more than 2% and reduced the rate of vertebral fractures by 30%–50% but did not significantly reduce nonvertebral fractures (Delmas et al., 2002; Ettinger et al., 1999). Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

Infertility. Clomiphene citrate is a potent antiestrogen that primarily is used for treatment of anovulation in the setting of an intact hypothalamic-pituitary axis and adequate estrogen production (e.g., PCOS) or to induce superovulation in women with unexplained infertility. By inhibiting the negative feedback effects of estrogen at hypothalamic and pituitary levels,
clomiphene increases FSH levels and thereby enhances follicular maturation. The drug is relatively inexpensive, is orally active, and requires less-extensive monitoring than do other fertility protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. Prolonged use (e.g., ≥ 12 cycles) may increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation.

**Experimental SERM-Estrogen Combinations.** There is considerable interest in MHT using combinations of a pure estrogen agonist (e.g., estriadiol) with a SERM that has predominantly antagonist activity in the breast and endometrium but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (e.g., prevention of hot flashes and bone loss) while the SERM blocks unwanted agonist action at peripheral sites (e.g., proliferative effects in breast and endometrium) but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie et al., 2003), but clinical efficacy and safety of this approach remain to be established.

**Estrogen Synthesis Inhibitors**

Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (Chapter 42). *Aminoglutethimide* inhibits aromatase activity, but its use is limited by its lack of selectivity and its side effects (sedation). It was discontinued in the U.S. in 2008.

The recognition that locally produced as well as circulating estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (Chapter 68). Both steroidal (e.g., formestane and exemestane) and nonsteroidal (e.g., anastrozole, letrozole, and vorozole) agents are available. Steroidal, or type I, agents are substrate analogues that act as suicide inhibitors to irreversibly inactivate aromatase, whereas the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes et al., 2003). *Exemestane, letrozole,* and *anastrozole* are currently approved in the U.S. for the treatment of breast cancer.

As discussed in Chapter 68, these agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in adjuvant use for postmenopausal women (Coombes et al., 2004), and they are indicated either following tamoxifen for 2–5 years or as initial agents. They have the added advantage of not increasing the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. They lack the beneficial effect of tamoxifen to maintain bone density and thus are usually administered with bisphosphonates. Their effects on plasma lipids remain to be established.

---

**Progestins**

**HISTORY Progestins**

Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it *progestin.* The next year, several European groups independently isolated the crystalline compound and called it *luteo-sterone,* unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name progestrone was a suitable compromise. Two major advances overcame the early difficulties and expense of obtaining progestrone from animal sources. The first was the synthesis of progestrone by Russel Marker from the plant product *diosgenin* in the 1940s, which provided a relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized norethindrone at Syntex, and Frank Colton, who synthesized the isomer *norethynodrel* at Searle. These advances led to the development of effective oral contraceptives.

**Chemistry**

Compounds with biological activities similar to those of progesterone are referred to as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 44–5) include the naturally occurring hormone progestrone, 17α-acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives in the estrane series, and norgestrel and related compounds in the gonane series. MPA and megestrol acetate are C21 steroids in the pregnancy family with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for MHT and other situations in which a selective progestational effect is desired. Furthermore, depot MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives (estranes) were developed for use as progestins in oral contraceptives, and although their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are another family of “19-nor” compounds, containing an ethyl rather than a methyl substituent in the 13 position. They have diminished androgenic activity relative to the estranes. These two classes of 19-nortestosterone derivatives are the progestational components of most oral and some long-acting injectable contraceptives. The remaining oral contraceptives contain a class of progestins derived from spironolactone (e.g., drospirenone) that have antiminerocorticoid and antiandrogenic properties.

The structural features of several progestins are shown in Figure 44–5. Unlike the ER, which requires a phenolic A ring for high-affinity binding, the PR favors a Δ3–3-one A-ring structure in an inverted 1β,2α-conformation. Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent on specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

**Biosynthesis and Secretion**

Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (Figure 44–3). LH, acting via its G protein–coupled receptor, stimulates progesterone secretion during the normal cycle.
Progestins have numerous metabolic actions. Progestins increase insulin sensitivity and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogues such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-nor-progestins may have more pronounced effects on plasma lipids because of their androgenic activity.

Medroxyprogesterone acetate decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but it does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly alter beneficial estrogen effects on either HDL or LDL profiles (Writing Group for the PEPI Trial, 1995); the spironolactone derivative drospirenone may actually have advantageous effects on the cardiovascular system due to its antiandrogenic and antimineralocorticoid activities. Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

**Pharmacology**

**Mechanism of Action**

A single gene encodes two isoforms of the PR, PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs...
by use of two distinct estrogen-dependent promoters in the PR gene (Giagrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Because the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present primarily in the nucleus in an inactive monomeric state to HSP90, HSP70, and p59. When receptors bind progesterone, the HSPs dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs located on target genes (Giagrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily via recruitment of coactivators such as SRC-1, NcoA-1, or NcoA-2 (Collingwood et al., 1999). The receptor-coactivator complex then favors further interactions with additional proteins, such as CBP and p300, which mediate other processes, including histone acetylation activity. Histone acetylation causes remodeling of chromatin that increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter. The biological activities of PR-A and PR-B are distinct and depend on the target gene. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that coactivators and corepressors interact differentially with PR-A and PR-B (e.g., the corepressor SMRT binds much more tightly to PR-A than to PR-B) (Giagrande et al., 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcretin and amphiregulin (Mulac-Jericevic et al., 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggested that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mulac-Jericevic et al., 2003). Certain effects of progesterone, such as increased Ca\(^{2+}\) mobilization in sperm, can be seen in as little as 3 min (Blackmore, 1999) and are therefore considered transcription independent. Similarly, progesterone can promote oocyte maturation (meiotic resumption) independent of transcription (Hammes, 2004).

**ADME**

Progestrone undergoes rapid first-pass metabolism, but high-dose (e.g., 100–200 mg) preparations of micronized progesterone are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone is also available in oil solution for injection, as a vaginal gel, as a slow-release IUD for contraception, and as a vaginal insert for assisted reproductive technology.

Esters such as MPA are available for intramuscular administration, and MPA and megestrol acetate may be used orally. The 19-nor steroids have good oral activity because the ethyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (see section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin but is not appreciably bound to SHBG. 19-Nor compounds, such as norethindrone, norgestrel, norgestrel, and desogestrel, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, 90% or less, but the proteins involved are compound specific.

The elimination \( t_{1/2} \) of progesterone is about 5 min, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3α,20α-diol; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer half-lives (e.g., ~7 h for norethindrone, 16 h for norgestrel, 12 h for gestodene, and 24 h for MPA). The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites.

**Antiprogestins and Progesterone Receptor Modulators**

The first report of an antiprogestin, RU 38486 (often referred to as RU-486) or mifepristone, appeared in 1981; this drug is available for the termination of pregnancy (Christin-Maire et al., 2000). In 2010, the FDA approved ulipristal acetate, a partial agonist at the progesterone receptor, for emergency contraception. Antiprogestins also have several other potential applications, including to prevent conception, to induce labor, and to treat uterine leiomyomas, endometriosis, menigiomas, and breast cancer (Spitz and Chwalisz, 2000).

**Mifepristone**

**Chemistry**

Mifepristone is a derivative of the 19-norpregestin norethindrone containing a dimethyl-a-aminophenol substituent at the 11β position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone is considered a PRM due to its context-dependent activity. Another widely studied antiprogestin is onapristone (or ZK 98299), which is similar in structure to mifepristone but contains a methyl substituent in the 13α rather than 13β orientation. More selective PRMs, such as asoprisnil, are being studied experimentally (DeManno et al., 2003).

**Pharmacological Effects**

Mifepristone acts primarily as a competitive receptor antagonist for both PRs, although it may have some agonist activity in certain contexts. In contrast, onapristone appears to be a pure progesterone antagonist. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and also appear to preferentially recruit corepressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uterine PRs. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of PRs in the uterus increases uterine PG levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending on the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.

If administered for one or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. PR blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1–2 weeks after antiprogestin treatment.
Mifepristone also binds to glucocorticoid and androgen receptors and exerts antiglucocorticoid and antiandrogenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of adrenocorticotropic hormone secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma.

**ADME**

Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared, with a plasma t½ of 20–40 h. In plasma, it is bound by α1-acid glycoprotein, which contributes to the drug’s long t½. Metabolites are primarily the mono- and didemethylated products (thought to have pharmacological activity) formed via CYP3A4. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces (Jang and Benet, 1997).

**Therapeutic Uses**

Mifepristone, in combination with misoprostol or other PGs, is available for the termination of early pregnancy. When mifepristone is used to produce a medical abortion, a PG is given 48 h after the antiprogestin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular sulprostone, intravaginal gemeprost, and oral misoprostol have been used. The success rate with such regimens is greater than 90% among women with pregnancies of 49 days’ duration or less. The most severe untoward effect is vaginal bleeding, which most often occurs within several hours, and the drug is slowly cleared, with a plasma t½ of 20–40 h. In plasma, it is bound by α1-acid glycoprotein, which contributes to the drug’s long t½. Metabolites are primarily the mono- and didemethylated products (thought to have pharmacological activity) formed via CYP3A4. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces (Jang and Benet, 1997).

**Perspective: Too Many People?**

The incredible growth of the earth’s human population stands out as one of the fundamental events of the last two centuries. The Old Testament dictum “be fruitful and multiply” (Genesis 9:1) has been followed too religiously by readers and nonreaders of the Bible alike. In 1798, Malthus started a great controversy by opposing the prevailing view of unlimited progress for humankind by making two postulates and a conclusion. Malthus postulated “that food is necessary for the existence of man” and that sexual attraction between female and male is necessary and likely to persist because “toward the extinction of the passion between the sexes, no progress whatever has hitherto been made,” barring “individual exceptions.” Malthus concluded that “the power of populations is infinitely greater than the power of the earth to produce subsistence for man,” producing a “natural inequality” that would someday doom “insurmountable in the way to perfectibility of society.”

Malthus was right: Passion between the sexes persists, and the power of populations is very great indeed, so much so that our sheer numbers have increased to the point that they are straining Earth’s capacity to supply food, energy, and raw materials to absorb the detritus of its human burden. Marine fisheries are being depleted, forests and aquifers are disappearing, and the atmosphere is accumulating greenhouse gases from combustion of the fossil fuels that provide the energy needs of 7 billion people, up from 1 billion in Malthus’s day. Perhaps some of the blame can be laid at the feet of medical science: Advances in public health and medicine have led to a significant decline in mortality and an increased life expectancy. However, medical science has also begun to assume a portion of the responsibility for overpopulation and its adverse effects. To this end, drugs in the form of hormones and their analogues have been developed to control human fertility.

**Ulipristal**

**Chemistry**

Ulipristal, a derivative of 19-norprogesterone, functions as a selective progesterone receptor modulator, acting as a partial agonist at PRs. Unlike mifepristone, ulipristal appears to be a relatively weak glucocorticoid antagonist.

**Pharmacological Effects**

In high doses, ulipristal has antiproliferative effects in the uterus; however, its most relevant actions to date involve its capacity to inhibit ovulation. Ulipristal’s antiiovulatory actions likely occur due to progesterone regulation at many levels, including inhibition of LH release through the hypothalamus and pituitary and inhibition of LH-induced follicular rupture within the ovary.

A 30-mg dose of ulipristal can inhibit ovulation when taken up to 5 days after intercourse. Ulipristal can block ovarian rupture at or even just after the time of the LH surge, confirming that at least some of its effects are directly in the ovary. Ulipristal may also block endometrial implantation of the fertilized egg, although whether this contributes to its effects as an emergency contraceptive is not clear.

**Therapeutic Uses**

Ulipristal acetate is licensed in the E.U. and the U.S. as an emergency contraceptive. Studies comparing ulipristal to levonorgestrel (progesterone-only emergency contraception) demonstrate that ulipristal is at least as effective when taken up to 72 h after unprotected sexual intercourse. In addition, ulipristal remains effective up to 120 h (5 days) after intercourse, making ulipristal a more versatile emergency contraceptive than levonorgestrel, which does not work well beyond 72 h after unprotected intercourse. The most severe side effect in clinical trials using ulipristal has been a self-limited headache and some abdominal pain.

**Hormonal Contraception**

**Types of Hormonal Contraceptives**

**Combination Oral Contraceptives.** The most frequently used agents in the U.S. are combination oral contraceptives containing both an estrogen and a progestin. These agents come in a variety of formulations and strengths (Table 44–2). Their theoretical efficacy generally is considered to be 99.9%. In practice, the 1-year failure rates of oral contraceptives are somewhat greater than 0.1% (Table 44–3). Combination oral contraceptives are available in many formulations. Almost all contain ethinyl estradiol as the estrogen and a 17a-alkyl-19-nortestosterone derivative as the progestin. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. (Virtually all preparations come as 28-day packs, with the pills for the last 7 days containing only inert ingredients.) For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “pill-free” period. The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day “off” period each month. However, several oral contraceptives are now available whereby progestin withdrawal is only induced every 3 months.

The estrogen content of current preparations ranges from 20 to 50 μg; most contain 30–35 μg. Preparations containing 35 μg or less of an estrogen are generally referred to as “low-dose” or “modern” pills. The dose of progestin is more variable because of differences in potency of the compounds used.

A transdermal preparation of norelgestromin and ethinyl estradiol is marketed for weekly application to the buttock, abdomen, upper arm, or torso for the first 3 consecutive weeks followed by a patch-free week for...
Hormonal Contraception: A Brief History

Around the beginning of the 20th century, a number of European scientists, including Beard, Prenant, and Loeb, developed the concept that secretions of the corpus luteum suppressed ovulation during pregnancy. The Austrian physiologist Haberlandt then produced temporary sterility in rodents in 1927 by feeding them ovarian and placental extracts—a clear example of an oral contraceptive. In 1937, Makepeace and colleagues demonstrated that pure progesterone blocked ovulation in rabbits, and Astwood and Fevold found a similar effect in rats in 1939.

In the 1950s, Pincus, Garcia, and Rock found that progesterone and 19-norprogestins prevented ovulation in women. Ironically, this finding grew out of their attempts to treat infertility with estrogen-progesterin combinations. The initial findings were that these treatments effectively blocked ovulation in most women. However, concern about cancer and other possible side effects of the estrogen they used (i.e., DES) led to the use of a progestin alone in their studies. One of the compounds used was norethynodrel, and early batches of this compound were contaminated with a small amount of mestranol. When mestranol was removed, it was noted that treatment with pure norethynodrel led to increased breakthrough bleeding and less-consistent inhibition of ovulation. Mestranol was thus reincorporated into the preparation, and this combination was employed in the first large-scale clinical trial of combination oral contraceptives.

Clinical studies in the 1950s in Puerto Rico and Haiti established the virtually complete contraceptive success of the norethynodrel/mestranol combination. In early 1961, Enovid (norethynodrel plus mestranol; no longer marketed in the U.S.) was the first “Pill” approved by the FDA for use as a contraceptive agent in the U.S.; this was followed in 1962 by approval for Ortho-Novum (norethindrone plus mestranol). By 1966, numerous preparations using either mestranol or ethinyl estradiol with a 19-norprogestin were available. In the 1960s, the progestin-only minipill and long-acting injectable preparations were developed and introduced.

Millions of women began using oral contraceptives, and frequent reports of untoward effects began appearing in the 1970s. The recognition that these side effects were dose dependent and the realization that estrogens and progestins synergistically inhibited ovulation led to the reduction of doses and the development of so-called low-dose or second-generation contraceptives. The increasing use of biphasic and triphasic preparations throughout the 1980s further reduced steroid dosages; it may be that currently used doses are the lowest that will provide reliable contraception. In the 1990s, the “third-generation” oral contraceptives, containing progestins with reduced androgenic activity (e.g., norgestimate and desogestrel), became available in the U.S. after being used in Europe. A variety of contraceptive formulations are currently available, including pills, injections, skin patches, subdermal implants, vaginal rings, and IUDs that release hormones.

Each 28-day cycle. A similar 3-week on/1-week off cycle is employed for the intravaginal ring containing ethinyl estradiol and etonogestrel.

Progestin-Only Contraceptives. Several agents are available for progestin-only contraception, with theoretical efficacies of 99%. Specific preparations include the “minipill”; low doses of progestins (e.g., 350 μg of norethindrone) taken daily without interruption; subdermal implants of 216 mg of norgestrel for long-term contraceptive action (e.g., up to 5 years) or 68 mg of etonogestrel for contraception lasting 3 years; and crystalline suspensions of MPA for intramuscular injection of 104 mg or 150 mg of drug. Each provides effective contraception for 3 months.

Intrauterine Devices. Two doses of levonorgestrel-releasing intrauterine systems (IUSs) are available in the U.S. The LNG20 contains 52 mg of levonorgestrel, which is initially released at a rate of 20 μg/d and declines gradually to 10–14 μg/d after 5 years. A smaller LNG IUS is available for women with a small uterine cavity or cervical stenosis and may result in less pain with insertion. The LNG14 contains 13.5 mg of levonorgestrel, which is initially released at a rate of 14 μg/d and declines to 5 μg/d after 3 years. A copper IUD, TCu380A, is also available in the U.S. It contains 380 mm of copper and is approved for 10 year’s use. The TCu380A may be preferred over an LNG IUS in women who desire long-term contraception and wish to avoid exogenous hormones and hormonal side effects and can also be used as an emergency contraceptive.

Mechanism of Action

Combination Oral Contraceptives. Combination oral contraceptives act by preventing ovulation. Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a midcycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. Although either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone diminishes the frequency of GnRH pulses. Because the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive action. Oral contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. The progestin component may also inhibit the estrogen-induced LH surge at midcycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick, viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation so effectively.

Progestin-Only Contraceptives. Progestin-only pills and levonorgestrel implants are highly efficacious but block ovulation in only 60%–80% of cycles. Their effectiveness is thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of IUDs that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Intrauterine Devices. While the contraceptive benefit of the LNG IUS is attributed to the progestin-mediated effects of thickening of cervical mucous and endometrial alterations, the contraceptive mechanism of the copper IUD is related to an inflammatory reaction within the endometrium that impairs sperm viability, motility, and fertilization.

Untoward Effects

Combination Oral Contraceptives. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors, and these drugs also provide many beneficial health effects (Burkman et al., 2004).

Unless otherwise indicated, the products are packaged with 21 active (hormone-containing) pills and 7 placebo tablets. For formulations that differ from this standard (e.g., multiphasic pills, extended-cycle formulations), the number of tablets of each pill strength are indicated.

*a Some formulations also contain iron to diminish the risk of iron deficiency anemia; these are not listed separately here.
*b Combination formulations contain both an estrogen and a progestin.
*Denotes continuous administration of active pills.

**Cardiovascular Effects.** The question of cardiovascular side effects has been reexamined for the newer low-dose oral contraceptives (Burkman et al., 2004). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). The risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Postmarketing epidemiologic studies indicated that women using transdermal contraceptives have a higher-than-expected exposure to estrogen and are at increased risk for the development of venous thromboembolism. Early high-dose combination oral contraceptives caused hypertension in 4%–5% of normotensive women and increased blood pressure in 10%–15% of those with preexisting hypertension. This incidence is much lower with newer low-dose preparations, and most reported changes in blood pressure are not significant. Estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant changes in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

**Cancer.** Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which contributors have since been removed from the market in the U.S. However, it is now clear that there is not a widespread association between oral contraceptive use and cancer (Burkman et al., 2004; Westhoff, 1999).

Epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about 2-fold but only in long-term (>5 years) users with persistent human papilloma virus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate there is about a doubling in the risk of liver cancer after 4–8 years of use. However, these are rare cancers, and the absolute increases are small.

The major concern is the carcinogenic effects of oral contraceptives is focused on breast cancer. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1–1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat (Westhoff, 1999).

Combination oral contraceptives decrease the incidence of endometrial cancer by 50%, an effect that lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez et al., 2001).

**Miscellaneous Effects.** Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day off period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-norprogestins.

**Progestin-Only Contraceptives.** Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases. No evidence indicates that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations. Acne may be a problem because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Headache is the most commonly reported untoward effect of depot MPA. Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. Many studies have found decreases in HDL levels and increases in LDL levels, and there have been several reports of decreased bone density. These effects may be
due to reduced endogenous estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6–12 months after the last injection. Progestrone-only medications have been associated with decreased bone mineral density, as noted by a black-box warning in the product label. Teenagers and younger women who have not achieved maximal bone density may be particularly at risk, although the data suggest that bone density returns to pretreatment levels fairly quickly after drug cessation. Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and, rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported, and acne is seen in some patients. Ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

Intrauterine Devices. Intrauterine devices are generally well tolerated, although complications related to the device and side effects related to the progestin can occur. Expulsion of the device is greatest in the first year and has been reported in 3%–6% of women with an LNG20 and 3.2% in women with an LNG14. Malposition of the device, extending into the myometrium or the endocervical canal, occurs in 10% of women and is associated with difficult placement, uterine distortion, and obesity. Not all malpositioned devices need to removed, as this condition is often asymptomatic and does not compromise the contraceptive efficacy of the device. Uterine perforation at the time of IUD insertion complicates approximately 1 in 1000 insertions. Symptoms of perforation may include pelvic pain and bleeding, although perforations are often asymptomatic. Surgical removal of the perforated IUD is preferred to minimize serious complications related to adhesions or perforation into the bowel, bladder, or blood vessels.

Pelvic inflammatory disease is infrequent at the time of insertion (1–10 per 1000 women undergoing insertion) and after insertion (1.4 women per 1000 women after insertion). Infections at the time of insertion or 1 month after insertion are generally related to new sexually transmitted infections. The LNG20 is associated with less risk of PID due to thickening of the cervical mucus. Oral antibiotic therapy may be attempted, and worsening infections should be treated with intravenous antibiotics and IUD removal.

Ectopic and intrauterine pregnancies rarely occur with an IUD in situ. Intrauterine pregnancies with an IUD in situ are at increased risk for adverse pregnancy outcomes if the IUD is left in place or removed. The decision to leave the IUD in place or remove it in pregnancy should be individualized based on the women’s obstetrical history, the trimester when it is diagnosed, and the anticipated difficulty of removing the IUD.

While device-related complications are infrequent, side effects related to the progestin are common. Irregular bleeding in the first 3–6 months after insertion and amenorrhea at 1 year after insertion are common. Complaints of side effects such as hirsutism, acne, weight change, nausea, headache, mood change, and breast tenderness are related to systemic effects of levonorgestrel and are the most common reason for discontinuation (approximately 12% of women with the LNG20). The copper IUD may be an alternative for women who discontinue the LNG IUS due to hormonal side effects, but it is associated with intermenstrual bleeding and increased volume of bleeding.

Contraindications

Modern oral contraceptives are considered generally safe in most healthy women; however, these agents can contribute to the incidence and severity of cardiovascular, thromboembolic, or malignant disease, particularly if other risk factors are present. Contraindications for combination oral contraceptive use are the following: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. The risk of serious cardiovascular side effects is particularly marked in women more than 35 years of age who smoke heavily (e.g., >15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Other relative contraindications include migraine headaches, hyper-tension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose pills should generally be used in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer.

The Centers for Disease Control and Prevention U.S. medical eligibility criteria list all progesterin-containing IUDs as category 2 for history of venous thromboembolism, which means a condition for which the advantages of using the method generally outweigh risks. The contraindications to IUDs are severe uterine distention, active pelvic infection, and unexplained abnormal uterine bleeding. The copper IUD should be avoided in women with Wilson disease or a copper allergy.

Noncontraceptive Health Benefits

Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. This protective effect persists for up to 15 years after oral contraceptive use is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of PID and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle cell disease (Collins, 1996).

From a purely statistical perspective, fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering the additional health benefits of these agents.

In addition to effective pregnancy prevention, the LNG20 reduces dysmenorrhea and menstrual blood loss. One year after insertion, 30%–40% of women experience amenorrhea. The LNG20 can also be used to prevent and treat endometrial hyperplasia, although close monitoring is necessary, as endometrial adenocarcinoma has occurred in LNG20 users. While LNG14 is effective at preventing pregnancy, less is known regarding the noncontraceptive benefits of the LNG14.

Postcoital Contraception

Postcoital (or emergency) contraception is indicated for use in cases of mechanical failure of barrier devices or in circumstances of unprotected intercourse (Cheng et al., 2008). Because it is less effective than standard oral contraceptive regimens, it is not intended as a regular method of contraception. The mechanisms of action of the postcoital contraceptives are not fully understood, but their efficacy clearly cannot be accounted for solely by the inhibition of ovulation. Other potential mechanisms of action include effects on gamete function and survival and on implantation. These agents do not affect established pregnancies.

A copper iud is more effective than oral emergency contraceptive agents and can provide ongoing pregnancy prevention. The copper IUD can be inserted within 5–7 days after an unprotected act after a negative pregnancy test.

Selective progesterone-receptor modulators (PRMs) such as ulipristal are approved as an emergency contraceptive, effective up to 120 h after unprotected intercourse. Mifepristone in oral doses ranging from 10 to 50 mg when taken within 5 days after unprotected intercourse can also be used, but is not FDA approved.
Plan B, which contains two tablets of the progestin levonorgestrel (0.75 mg each), is marketed specifically for postcoital contraception and may be obtained in the U.S. without a prescription by women 18 years of age and older. Treatment is most effective if the first dose is taken within 72 h of intercourse, followed by a second dose 12 h later; a single dose of 1.5 mg within 72 h of intercourse appears to be equally effective.

**Termination of Pregnancy**

If contraception is not used or fails, either mifepristone (RU–486) or methotrexate (50 mg/m² intramuscularly or orally) can be used to terminate an unwanted pregnancy in settings outside surgical centers. A PG then is administered to stimulate uterine contractions and expel the detached conceptus; in the U.S., PGs used include dinoprost (PGE₂), administered vaginally or the PGE₂ analogue misoprostol given orally or vaginally, both of which are used off label for this purpose. PGs used in other countries include the PGE₂ analogue sulprostone and the PGE₂ analogue gemeprost.

Mifepristone (600 mg) is FDA-approved for pregnancy termination within 49 days after the start of a woman’s last menstrual period. The synthetic PGE₂ analogue misoprostol (400 μg) is administered orally 48 h later; vaginal administration is at least as effective but is not FDA approved. Complete abortion using this procedure exceeds 90%; when termination of pregnancy fails or is incomplete, surgical intervention is required. Other published regimens include lower doses of mifepristone (200 or 400 mg) and different time intervals between the mifepristone and misoprostol. Finally, repeated doses of misoprostol alone (e.g., 400 μg vaginally or sublingually every 2 h or every 12 h for three doses) also have been effective in settings where mifepristone is unavailable. Vaginal bleeding follows pregnancy termination and typically lasts from 1 to 2 weeks but rarely (in 0.1% of patients) is severe enough to require blood transfusion. A high percentage of women also experience abdominal pain and uterine cramps, nausea and vomiting, and diarrhea secondary to the PG. Myocardial ischemia and infarction have been reported in association with sulprostone and gemeprost.

Because mifepristone carries a risk of serious, and sometimes fatal, infections and bleeding following its use for medical abortion, a black-box warning has been added to the product labeling. Fulminant septic shock associated with Clostridium sordellii infections may result and is attributable to the combined effects of uterine infection and inhibition of glucocorticoid action by mifepristone (Cohen et al., 2007). Patients who develop symptoms and signs of infection, especially marked leukocytosis even without fever, should be treated aggressively with antibiotics effective against anaerobic organisms such as C. sordellii (e.g., penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole).

**Induction of Ovulation**

Infertility (i.e., the failure to conceive after 1 year of unprotected sex) affects about 10%–15% of couples in developed nations and is increasing in incidence as more women choose to delay childbearing until later in life. The cause of infertility is attributed primarily to the woman in approximately one-third of cases, to the man in approximately one-third, and to both in approximately one-third.

Anovulation accounts for about 50% of female infertility and is a major focus of pharmacological interventions used to achieve conception. Although a history of regular cyclic bleeding is strong presumptive evidence for ovulation, assessment of urine LH levels with an ovulation predictor kit or measurement of the serum progesterone levels during the luteal phase provides more definitive information. Evaluation of anovulation may uncover PCOS, thyroid disorders, hyperprolactinemia, or hypogonadism, but the cause is often idiopathic.

A number of approaches have been used to stimulate ovulation in anovulatory women. Often, a stepwise approach is taken, initially using simpler and less-expensive treatments, followed by more complex and expensive regimens if initial therapy is unsuccessful.

**Clomiphene**

Clomiphene citrate was reviewed previously in this chapter. A typical regimen is 50 mg/d orally for 5 consecutive days starting between days 2 and 5 of the cycle in women who have spontaneous uterine bleeding or following a bleed induced by progesterone withdrawal in women who do not. If this regimen fails to induce ovulation, the dose of clomiphene is increased, first to the FDA-approved maximum of 100 mg/d and possibly to higher levels of 150 or 200 mg/d. Although clomiphene is effective in inducing ovulation in perhaps 75% of women, successful pregnancy ensues in only 40%–50% of those who ovulate. This has been attributed to clomiphene’s inhibition of estrogen action on the endometrium, resulting in an environment that is not optimal for fertilization or implantation.

**Aromatase Inhibitors**

Aromatase inhibitors (e.g., letrozole, 2.5–7.5 mg/d for 5 days, typically starting on day 3 of the cycle) induce follicle development by inhibiting estrogen biosynthesis, thus decreasing estrogen negative feedback and increasing FSH levels and follicle development. In comparing letrozole and clomiphene for ovulation induction in women with PCOS and infertility, letrozole was associated with a higher pregnancy and live birth rate (Legro et al., 2014). Letrozole is associated with fewer estrogen deprivation side effects (hot flashes, mood change) and possibly fewer multifetal gestations than clomiphene.

**Gonadotropins**

The preparations of gonadotropins available for clinical use are detailed in Chapter 42. Gonadotropins are indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, gonadotropins also are used to induce ovulation in women with PCOS who do not respond to clomiphene.

Given the marked increases in maternal and fetal complications associated with multifetal gestation, the goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant oocyte.
Figure 44–6  Idealized regimens using exogenous gonadotropins for induction of fertility. A. Step-up regimen for ovulation induction. After menses, daily injections of gonadotropin (75 IU) are started. Follicle maturation is assessed by serial measurement of plasma estradiol and follicle size, as discussed in the text. If an inadequate response is seen, the dose of gonadotropin is increased to 112 or 150 IU/d. When one or two follicles have achieved a diameter of 17 mm or greater, final follicle maturation and ovulation are induced by injection of hCG. Fertilization then is achieved at 36 h after hCG injection by intercourse or intrauterine insemination (IUI). If more than two mature follicles are seen, the cycle is terminated, and barrier contraception is used to avoid multifetal pregnancy.

To complete follicular maturation and induce ovulation, hCG (5000–10,000 IU) is given 1 day after the last dose of gonadotropin. Fertilization of the oocyte(s) at 36 h after hCG administration then is attempted, by either intercourse or intrauterine insemination.

Gonadotropin induction also is used for ovarian stimulation in conjunction with IVF (Figure 44–6; Macklon et al., 2006). In this setting, larger doses of FSH (typically 225–300 IU/d) are administered to induce the maturation of multiple (ideally at least 5 and up to 20) oocytes that can be retrieved for IVF. To prevent the LH surge and subsequent premature luteinization of the ovarian follicles, gonadotropins typically are administered in conjunction with a GnRH agonist or a GnRH antagonist. The length of the IVF protocol is predicated by the initial flare of gonadotropin secretion that occurs in response to the GnRH agonists. In the long protocol, the agonist is started in the luteal phase of the previous cycle (generally on cycle day 21) and then maintained until the time of hCG injection to induce ovulation. Alternatively, in the “flare” protocol, the GnRH agonist is started on cycle day 2 (immediately after the start of menses), and gonadotropin injections are added 1 day later. In the GnRH antagonist “short protocol,” the antagonist can be used to inhibit endogenous LH secretion and is typically started after follicular recruitment is initiated. Current regimens include daily injection in a dose of 0.25 mg (ganirelix or cetrorelix) starting on the fifth or sixth day of gonadotropin stimulation or a single dose of 3 mg of cetrorelix administered on day 8 or 9 of the late follicular phase. Adequate follicle maturation typically takes 8–12 days after gonadotropin therapy is initiated.
HORMONES AND HORMONE ANTAGONISTS

Using either the long or short protocols, hCG (at typical doses of 5000–10,000 IU of urine-derived product or 250 μg of recombinant hCG) is given to induce final oocyte development, and the mature eggs are retrieved from the preovulatory follicles at 36 h thereafter. The ova are retrieved by transvaginal ultrasound-guided aspiration and fertilized in vitro with sperm (IVF) or by intracytoplasmic sperm injection; one or two embryos then are transferred to the uterus 3–5 days after fertilization.

Because of the inhibitory effects of GnRH agonists or antagonists on pituitary gonadotropes, the secretion of LH that normally sustains the corpus luteum after ovulation does not occur. Repeated injections of hCG, while sustaining the corpus luteum, may increase the risk of OHSS. Thus, standard IVF regimens typically provide exogenous progesterone replacement to support the fetus until the placenta acquires the biosynthetic capacity to take over this function; regimens include progesterone in oil (50–100 mg/d intramuscularly) or micronized progesterone (180–300 mg twice daily vaginally). Vaginal preparations containing 100 or 90 mg of micronized progesterone are approved for administration two or three times daily as part of IVF.

Aside from the attendant complications of multifetal gestation, the major side effect of gonadotropin treatment is OHSS. This potentially life-threatening event is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal cavity, thorax, and even the pericardium. Symptoms and signs include abdominal pain or distention, nausea and vomiting, diarrhea, dyspnea, oliguria, and marked ovarian enlargement on ultrasonography. OHSS can lead to hypovolemia, electrolyte abnormalities, acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction.

In an effort to minimize OHSS in at-risk patients, the FSH can be withheld for a day or two (“coasting”). The rationale for this approach is that larger follicles become relatively gonadotropin independent and thus will continue to mature, while the smaller follicles undergo atresia in response to gonadotropin deprivation. Alternatively, an endogenous LH surge can be induced with a GnRH agonist during a GnRH antagonist short protocol, which nearly eliminates the incidence of OHSS by avoiding the use of hCG to trigger oocyte maturation.

The potential deleterious effects of gonadotropins are debated. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial (Brinton et al., 2005).

**Insulin Sensitizers**

Polycystic ovary syndrome affects 4%–7% of women of reproductive age and is the most frequent cause of anovulatory infertility. Inasmuch as patients with PCOS often exhibit hyperinsulinemia and insulin resistance, insulin sensitizers such as metformin have been evaluated for their effects on ovulation and fertility (see Chapter 47). Although several small trials suggested that metformin increased ovulation relative to placebo in women with PCOS, a trial failed to demonstrate a significant effect of metformin on fertility (Legro et al., 2007); metformin was less effective than clomiphene in inducing ovulation, promoting conception, or improving live birth rates, and there was no benefit of combining metformin with clomiphene on live births, except possibly in women resistant to clomiphene. Thus, except in women who exhibit glucose intolerance, the consensus is that metformin generally should not be used for fertility induction in women with PCOS (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

Thiazolidinediones also have been evaluated for their ability to induce ovulation in patients with PCOS but are not used for this indication given an increased risk of congestive heart failure and myocardial ischemia.

**Drug Therapy in Obstetrics**

**Pregnancy-Induced Hypertension/Preeclampsia**

Hypertension affects up to 10% of pregnant women in the U.S. Hypertension that precedes pregnancy or manifests before 20 weeks of gestation is believed to overlap considerably in pathogenesis with essential hypertension. These patients appear to be at increased risk for gestational diabetes and need careful monitoring. In contrast, pregnancy-induced hypertension, or preeclampsia, generally presents after 20 weeks of gestation as a new-onset hypertension with proteinuria (> 300 mg of urinary protein/24 h); preeclampsia is thought to involve placenta-derived factors that affect vascular integrity and endothelial function in the mother, thus causing peripheral edema, renal and hepatic dysfunction, and in severe cases, seizures. Chronic hypertension is an established risk factor for preeclampsia. The consensus panel recommended initiation of drug therapy in women with a diastolic blood pressure > 105 mm Hg or a systolic blood pressure > 160 mm Hg. If severe preeclampsia ensues, with marked hypertension and evidence of end-organ damage, then termination of the pregnancy by delivery of the baby is the treatment of choice, provided that the fetus is sufficiently mature to survive outside the uterus. If the baby is very preterm, then hospitalization and pharmacotherapy may be employed in an effort to permit further fetal maturation in utero.

Several drugs commonly used for hypertension in non-pregnant patients (e.g., angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists) should not be used in pregnant women due to unproven evidence of adverse fetal effects. Many experts will convert the patient to the centrally acting adrenergic agonist α-methyl dopa (250 mg twice daily) (FDA Category B), which rarely is used for hypertension in non-pregnant patients. Other drugs with reasonable evidence of safety (Category C) also may be used, including the combination α₂-selective, β-nonselective adrenergic antagonist labetalol (100 mg twice daily) and the Ca²⁺ channel blocker nifedipine (30 mg once daily).

If severe preeclampsia or impending labor requires hospitalization, blood pressure can be controlled acutely with hydralazine (5 or 10 mg IV or IM, with repeated dosing at 20-min intervals depending on blood pressure response) or labetalol (20 mg IV, with dose escalation to 40 mg at 10 min if blood pressure control is inadequate). In addition to receiving drugs for blood pressure control, women with severe preeclampsia or who have CNS manifestations (e.g., headache, visual disturbance, or altered mental status) are treated as inpatients with magnesium sulfate, based on its documented efficacy in seizure prevention and lack of adverse effects on the mother or baby. Such treatment also should be considered for postpartum women with CNS manifestations: 20% of episodes of eclampsia occur in women more than 48 h post-delivery.

**Prevention of Preeclampsia**

**Prevention of Preterm Labor**

**Scope of the Problem and Etiology**

Preterm birth, defined as delivery before 37 weeks of gestation, occurs in more than 10% of pregnancies in the U.S. and is increasing in frequency; it is associated with significant complications, such as neonatal respiratory distress syndrome, pulmonary hypertension, and intracranial hemorrhage. Although incompletely understood, risk factors for preterm labor include multifetal gestation, premature rupture of the membranes, intrauterine infection, and placental insufficiency. The more premature the baby, the greater the risk of complications, prompting efforts to prevent or interrupt preterm labor.

The therapeutic objective in preterm labor is to delay delivery so that the mother can be transported to a regional facility specializing in the care of premature babies and supportive agents can be administered; such supportive treatments include glucocorticoids to stimulate fetal lung maturation (see Chapter 46) and antibiotics (e.g., erythromycin, ampicillin) to diminish the frequency of neonatal infection with group B β-hemolytic Streptococcus. Based on concerns over deleterious effects of antibiotic therapy, it is essential that antibiotics not be administered indiscriminately to all women thought to have preterm labor, but rather be reserved for those with premature rupture of the membranes and evidence of infection.

**Prevention of Preterm Labor: Progesterone Therapy**

Progesterone levels in some species diminish considerably in association with labor, whereas administration of progesterone inhibits the secretion...
of pro-inflammatory cytokines and delays cervical ripening. Thus, progesterone and its derivatives have long been advocated to diminish the onset of preterm labor in women at increased risk due to previous preterm delivery. Despite considerable controversy, recent randomized trials have revived interest in this approach. Hydroxyprogesterone caproate at a dose of 250 mg administered weekly by intramuscular injection has been shown to reduce preterm birth by about one-third in women with a prior preterm birth of a singleton. Vaginal administration of progesterone (200 mg each night) has been shown to reduce preterm birth in women with midtrimester cervical shortening by ultrasound examination. The role of progesterone for prevention of preterm birth in multiple gestations is controversial.

**Tocolytic Therapy for Established Preterm Labor**

Inhibition of uterine contractions of preterm labor, or *tocolysis*, has been a focus of therapy (Simhan and Caritis, 2007). Although tocolytic agents delay delivery in about 80% of women, they neither prevent premature births nor improve adverse fetal outcomes such as respiratory distress syndrome.

Specific tocolytic agents include β adrenergic receptor agonists, MgSO₄, Ca²⁺ channel blockers, COX inhibitors, oxytocin receptor antagonists, and NO donors. The mechanisms of action of these agents are illustrated in Figure 44–7.

The β adrenergic receptor agonists relax the myometrium by activating the cyclic AMP-PKA signaling cascade that phosphorylates and inactivates MLCK, a key enzyme in uterine contraction. **Ritodrine**, a selective β₂ agonist, was specifically developed as a uterine relaxant and remains logically induction.

**Initiation of Labor**

Labor induction is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of delivery or pharmacological induction.

**Prostaglandins and Cervical Ripening**

Prostaglandins play key roles in parturition (see Chapter 37). Thus, PGE₂, PGF₁α, and PGF₂α are used to facilitate labor by promoting ripening and dilation of the cervix. They can be administered either orally or via local administration (either vaginally or intracervically). The ability of certain of adverse maternal effects, including tachycardia, hypotension, and pulmonary edema.

Similarly, Ca²⁺ channel blockers inhibit the influx of Ca²⁺ through depolarization-activated, voltage-sensitive Ca²⁺ channels in the plasma membrane, thereby preventing the activation of MLCK and the stimulation of uterine contraction. **Nifedipine**, the Ca²⁺ channel blocker used most commonly for this purpose, can be administered parenterally or orally. Relative to β₂ adrenergic agonists, nifedipine is more likely to improve fetal outcomes and less likely to cause maternal side effects.

Based on the role of PGs in uterine contraction, COX inhibitors (e.g., indomethacin) have been used to inhibit preterm labor, and some data suggest that they may reduce the number of preterm births. Because they also can inhibit platelet function and induce closure in utero of the ductus arteriosus, these inhibitors should not be employed in term pregnancies (or in pregnancies beyond 32 weeks of gestation, when the risk of severe complications of prematurity is relatively lower). Short courses of treatment (<72 h) pose less risk for impaired circulation in the fetus.

Despite numerous clinical trials, the superiority of any one therapy has not been established, and none of the drugs has been shown definitively to improve fetal outcome.

**Figure 44–7 Sites of action of tocolytic drugs in the uterine myometrium.** The elevation of cellular Ca²⁺ promotes contraction via the Ca²⁺/calmodulin-dependent activation of MLCK. Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of MLCK. Pharmacological manipulations to reduce myometrial contraction include the following: (1) inhibiting Ca²⁺ entry (Ca²⁺ channel blockers, MgSO₄); (2) reducing mobilization of intracellular Ca²⁺ by antagonizing GPCR-mediated activation of the Gq-PLC-IP₃-Ca²⁺ pathway (with antagonists of the FP and OXT receptors) or reducing production of the FP agonist, PGF₂α (with COX inhibitors); (3) enhancing relaxation by elevating cellular cAMP (with β₂ adrenergic agonists that activate Gs-AC) and cellular cGMP (with NO donors that stimulate sGC). Note that pharmacological activators of sGC (e.g., riociguat) are contraindicated in pregnancy (see Chapter 31). AC, adenylyl cyclase; COX, cyclooxygenase; FP, the PGF₂α receptor; OXYT, the oxytocin receptor; PLC, phospholipase C; sGC, soluble guanylyl cyclase.
HORMONES AND HORMONE ANTAGONISTS

Menopause refers to the permanent cessation of menstrual periods (i.e., for > 12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age. The incidence of fractures in postmenopausal women is increased for this purpose, it is administered by intravenous infusion of a diluted solution, preferably via an infusion pump. Current protocols start with an initial dose of 0.5 μg/min, which is increased every 10 min to a maximum of 5 μg/min. The total dose should not exceed 20 μg. Adverse effects include uterine hyperstimulation and, rarely, uterine rupture. Misoprostol should be discontinued for at least 3 h before initiating oxytocin therapy.

Oxytocin

The structure and physiology of oxytocin are discussed in Chapter 42. This section presents therapeutic uses of oxytocin in obstetrics, which include the induction of labor, the augmentation of labor that is not progressing, and the prophylaxis or treatment of postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm” (Clark et al., 2009), and its role and specific application to most deliveries in the U.S. remain open to debate. Thus, careful review of the appropriate indications for oxytocin administration and attention to the dose and progress of labor during induction are essential.

Labor Induction. Oxytocin is the drug of choice for labor induction; for this purpose, it is administered by intravenous infusion of a diluted solution, preferably via an infusion pump. Current protocols start with an oxytocin dose of 6 μIU/min, followed by advancement of dose as needed, up to 40 μIU/min. Uterine hyperstimulation should be avoided; however, if it occurs, as evidenced by too-frequent contractions (more than five contractions in a 10-min interval) or the development of uterine tetany, the oxytocin infusion should be discontinued immediately. Because the T1/2 of intravenous oxytocin is relatively short (12–15 min), the hyperstimulatory effects of oxytocin will dissipate fairly rapidly after the infusion is discontinued. Thereafter, the infusion can be reinitiated at a dose of half that at which hyperstimulation occurred and increased cautiously as tolerated.

Because of its structural similarity to vasopressin, oxytocin at higher doses activates the vasopressin V2 receptor and has antidiuretic effects. Particularly if hypotonic fluids (e.g., dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Dysfunctional Labor. Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions in dysfunctional labor, an infusion rate of 10 μIU/min typically is sufficient; doses in excess of 40 μIU/min rarely are effective when lower concentrations fail. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion.

Menopause and Hormone Therapy

Menopause refers to the permanent cessation of menstrual periods (i.e., for > 12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age. The decline in estradiol levels produces a variety of symptoms and signs, including vasomotor disturbances (hot flashes or flushes), sweating, irritability, sleep disturbances, and atrophy of estrogen-dependent tissue. In addition, postmenopausal women are at increased risk for osteoporosis, bone fractures, and CHD and experience increased memory loss and other cognitive difficulties.

Estrogens

Estrogens are most commonly used to treat vasomotor disturbances (“hot flashes”) in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. A variety of preparations, including oral, transdermal, and vaginal, are available. Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic end point.

In postmenopausal women with an intact uterus, a progestin is included to prevent endometrial cancer. MPA is used in the U.S., but micronized progesterone is preferred; norethindrone and norgestrel/levonorgestrel are also commonly used. Women without a uterus are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

The two major uses of estrogens are for MHT and as components of combination oral contraceptives, and the pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated equine estrogens have been the most common agents for postmenopausal use (0.625 mg/d). In contrast, most combination oral contraceptives in current use employ 20–35 μg/d of ethinyl estradiol. These preparations differ widely in their oral potencies (e.g., a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5–10 μg of ethinyl estradiol). Thus, the “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, in the last two decades, the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35-μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (e.g., with oral contraceptives that contained 30–150 μg of ethinyl estradiol or mestranol).

Menopausal Hormone Therapy

The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

Vasomotor Symptoms

The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered. MPA may provide some relief of vasomotor symptoms for certain patients, and the α-adrenergic agonist clonidine diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose, the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

Osteoporosis

Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (Chapter 48). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (e.g., death and permanent disability) are a major public health problem, especially as the population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs, such as bisphosphonates, should be considered (Chapter 48). Most fractures in the postmenopausal period

825
occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Anderson et al., 2004; Rossouw et al., 2002). Estrogens act primarily to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Belchetz, 1994; Prince et al., 1991). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. An appropriate diet with adequate intake of Ca²⁺ and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment.

**Vaginal Dryness and Urogenital Atrophy**

Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

**Cardiovascular Disease**

The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. However, estrogens promote coagulation and thromboembolic events. Randomized prospective studies unexpectedly have indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time (Grady et al., 2002; Rossouw et al., 2002). Combined estrogen-progestin therapy is associated with a decrease in heart attacks in younger women.

**Other Therapeutic Effects**

Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes, including headache, fatigue, and difficulty concentrating. Chronic lack of sleep created by hot flashes and other vaso-motor symptoms may be contributing factors. Estrogen replacement may help alleviate or lessen some of these via direct actions (e.g., improvement of vaso-motor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994). The WHI demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw et al., 2002).

**Menopausal Hormone Regimens**

In the 1960s and 1970s, there was an increase in estrogen-replacement therapy, or ERT (i.e., estrogens alone) in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. About 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of hormone-replacement therapy (HRT), which includes a progestin to limit estrogen-related endometrial hyperplasia. Postmenopausal HRT, when indicated, should include both an estrogen and progestin for women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins. Conjugated estrogens and MPA historically have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estradiol acetate have been used as estrogens, and norethindrone, norgestiminate, levonorgestrel, norethisterone, and progesterone also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12–14 days of estrogen treatment; and (3) 5–6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. Conjugated estrogens plus MPA given for a fixed dose daily and conjugated estrogens given for 28 days plus MPA given for 14 of 28 days are widely used combination formulations. Other combination products available in the U.S. are ethinyl estradiol plus norethindrone acetate, estradiol plus norethindrone, estradiol and norgestimate, and estradiol and drospirenone. Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than does transdermal administration and may increase SHBG, other binding globulins, and angiotensinogen and possibly the cholesterol content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (~50% of those seen with the oral route) (Waldh et al., 1994).

Tibolone is widely used in the E.U. for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the U.S. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The effects of this drug on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Regardless of the specific agent or regimen, MHT with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

**Untoward Responses**

The use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5- to 15-fold (Shapiro et al., 1985). This increased risk can be prevented if a progestin is coadministered with the estrogen (Pike et al., 1997), and this is now standard practice.

The association between estrogen or estrogen-progestin use and breast cancer is of great concern. The results of two large randomized clinical trials of estrogen/progestin and estrogen only (i.e., the two arms of WHI) in postmenopausal women clearly established a small but significant increase in the risk of breast cancer in the CEE+MPA studies (CEE, conjugated equine estrogens) (Anderson et al., 2004; Rossouw et al., 2002). In the WHI study, CEE+MPA was associated with an increased relative risk of breast cancer by 25%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received CEE alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance. Interestingly, the incidence of colon cancer was reduced by 26% in the WHI trial.

The Million Women Study (MWS) in the U.K. was a cohort study rather than a clinical trial (Beral et al., 2003). It surveyed more than 1 million women; about half had received some type of hormone treatment, and half had never used this type of treatment. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and MWS data are thus consistent with earlier studies indicating that the progestin component (e.g., medroxyprogesterone) in combined HRT plays a major role in this increased risk of breast cancer (Ross et al., 2006; Schairer et al., 2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy. Thus, HRT for 5 years or less is often prescribed to mitigate hot flashes and likely has a minimal effect on the risk of breast cancer.
Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. However, if catechol estrogens, especially the 4-hydroxycatechols, are converted to semiquinones or quinones prior to “inactivation” by COMT, the generation of ROSs may cause direct chemical damage to DNA bases (Yue et al., 2003). In this regard, CYP1B1, which has specific estrogen 4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers.

Metabolic and Cardiovascular Effects

Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, addition of progestins may reduce the favorable actions of estrogens. Estrogens do increase cholesterol levels in bile and cause a relative 2- to 3-fold increase in gallbladder disease. Currently, prescribed doses of estrogens generally do not increase the risk of hypertension, and estrogen engaging the ERβ receptor typically reduces blood pressure.

Many studies and clinical trials suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35%–50% (Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. The HER2 study followed women with established CHD and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, but there was no overall change in 5 years (Hulley et al., 1998). The HER2 II follow-up found no overall change in the incidence of CHD after 6.8 years of the treatment (Grady et al., 2002). In women without existing CHD (WHI trials), treated with an estrogen plus progestin, protective effects were seen but only when hormone replacement was initiated within 10 years of menopause (Rossouw et al., 2002).

It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with preexisting cardiovascular disease (Grady et al., 2000). The increase in absolute risk is small but significant. In the WHI, for example, an estrogen-progestin combination led to an increase in eight attributable cases of stroke per 10,000 older women and a similar increase in pulmonary embolism (Rossouw et al., 2002). The latter was seen mainly in women who concomitantly smoked cigarettes.

Effects on Cognition

Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer disease (Green and Simpkins, 2000). However, the Women’s Health Initiative Memory Study (WHIMS) of a group of women 65 years of age or older found that estrogen-progestin therapy was associated with doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp et al., 2003; Shumaker et al., 2003).

Other Potential Untoward Effects

Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just before sleep. Fullness and tenderness of the breasts and edema may occur, but sometimes can be diminished by lowering the dose.

Drug Therapy in Endometriosis, Hirsutism, and Gender Transition

Endometriosis

Endometriosis is an estrogen-dependent disorder that results from endometrial tissue ectopically located outside the uterine cavity (Farquhar, 2007). It predominantly affects women during their reproductive years, with a prevalence of 0.5%–5% in fertile women and 25%–40% in infertile women. Diagnosis typically is made at laparoscopy, either prompted by unexplained pelvic pain (dysmenorrhea or dyspareunia) or infertility. Although poorly understood, the infertility is thought to reflect involvement of the fallopian tubes with the underlying process and, possibly, impaired oocyte maturation.

Because the proliferation of ectopic endometrial tissue is responsive to ovarian steroid hormones, many symptomatic approaches to therapy aim to produce a relatively hypoestrogenic state. Combination oral contraceptives have been standard first-line treatment of symptoms of endometriosis, and ample evidence from observational trials supports their benefit. The predominant mechanism of action is believed to be suppression of gonadotropin secretion, with subsequent inhibition of estrogen biosynthesis. Progestins (e.g., medroxyprogesterone, dienogest) also have been used to promote decidualization of the ectopic endometrial tissue. The levonorgestrel IUS, which is approved for contraception, also has been used off label for this indication, as well as for menorrhagia.

Stable GnRH agonists can suppress gonadotropin secretion and thus effect medical castration. Drugs that carry an indication for endometriosis include leuprolide, goserelin, and nafarelin; other GnRH agonists also may be used off label for this purpose (see Chapter 42). Due to significant decreases in bone density and symptoms of estrogen withdrawal, “add-back” therapy with either a low-dose synthetic estrogen (e.g., conjugated equine estrogens, 0.625–1.25 mg) or a high-dose progestin (e.g., norethindrone, 5 mg) has been used when the duration of therapy has exceeded 6 months (Olive, 2008). Danazol, a synthetic androgen that inhibits gonadotropin production via feedback inhibition of the pituitary-ovarian axis, also is FDA approved for endometriosis therapy; it rarely is used now because of its significant adverse effects, including hirsutism and elevation of hepatic transaminases. In Europe and elsewhere, the antiprogestin gestrinone has been employed. By virtue of their ability to block the terminal step in estrogen biosynthesis, inhibitors of aromatase are under investigation for endometriosis (reviewed by Barbieri, 2008).

Hirsutism

Hirsutism, or increased hair growth in the male distribution, affects about 10% of women of reproductive age. It can be a relatively benign, idiopathic process or part of a more severe disorder of androgen excess that includes overt virilization (voice deepening, increased muscle mass, male pattern balding, clitoromegaly) and often results from ovarian or adrenal tumors. Specific etiologies associated with hirsutism include congenital adrenal hyperplasia, PCOS, and Cushing syndrome. After excluding serious pathology such as a steroid-producing malignancy, the treatment largely becomes empirical (Martin et al., 2008).

Pharmacotherapy is directed at decreasing androgen production and action. Initial therapy often involves treatment with combination oral contraceptive pills, which suppress gonadotropin secretion and thus the production of ovarian androgens. The estrogen also increases the concentration of SHBG, thereby diminishing the free concentration of testosterone. The full effect of this suppression may take up to 6–9 months. GnRH agonists downregulate gonadotropin secretion and also may be used to suppress ovarian steroid production.

In patients who fail to respond to ovarian suppression, efforts to block androgen action may be effective. Spironolactone, a mineralocorticoid receptor antagonist, and flutamide (see Chapter 45) inhibit the androgen receptor. In Europe and elsewhere, cyproterone (50–100 mg/d) is used as an androgen receptor blocker, often in conjunction with a combination oral contraceptive. Finasteride, an inhibitor of the type 2 isozyme of 5α-reductase that blocks the conversion of testosterone to dihydrotestosterone also is effective. Male offspring of women who become pregnant while taking any of these androgen inhibitors are at risk of impaired virilization secondary to impaired synthesis or action of dihydrotestosterone (pregnancy risk FDA category X; see Appendix I). The antifungal ketoconazole, which inhibits CYP steroid hydroxylases (see Chapters 46 and 61), also can block androgen biosynthesis but may cause liver toxicity. Topical eflornithine, an ornithine decarboxylase inhibitor, has been used with some success to decrease the rate of facial hair growth.

Nonpharmacological approaches include bleaching, depilatory treatments (e.g., shaving, treatment with hair-removing chemicals), or methods that remove the entire hair follicle (e.g., plucking, electrolysis, laser ablation).
Gender Transition
In the past 10–20 years, sex steroids have been used more frequently in transgender patients. Because no significant clinical trials have been performed, a great deal of variability exists in the approaches taken in both male-to-female and female-to-male transgender patients. In general, younger patients in their early teens are often held from natural puberty through the use of GnRH agonists until the individuals are old and mature enough to be certain of their decision. Once the decision is made, whether the patients are younger or older, the approaches can be myriad, although they follow the same principals: (1) suppress endogenous sex steroid production and (2) promote physical and mental features of the desired gender.

Male-to-Female Transitions
The primary medication used for male-to-female transition is some form of estrogen, whether it be oral estradiol (2–6 mg per day), transdermal estradiol (0.1–0.4 mg every 24 h), or injectable estrogens such as estradiol valerate or estradiol cypionate (5–10 mg IM every 2 weeks). Side effects with estrogens, including thrombosis and breast cancer (not really established in male-to-female transgender patients) must be discussed with patients. Target serum estradiol levels are usually in the range of 100–200 pg/mL. In many patients, estrogen treatment alone will be sufficient to suppress endogenous androgen production and therefore androgen-mediated effects; however, in patients where this is not possible, antiandrogens such as spironolactone (100–400 mg per day) can be used. Alternatively, endogenous androgen production can be suppressed with GnRH agonists. The advantage of using antiandrogens or GnRH agonists is that the dosages of estradiol can often be significantly lower.

Female-to-Male Transitions
The primary medication used in female-to-male transitions is some form of androgen, whether it be injectable, such as testosterone enanthate or cypionate (50–100 mg IM per week), or androgen gels (25–100 mg per day of testosterone). Target plasma androgen levels should be in the normal male range (300–500 mg per day). Side effects of excess androgens, including polycythemia and lipid abnormalities, should be discussed and monitored with all patients. In general, these doses of androgens are sufficient to suppress endogenous ovarian steroid hormone production; however, if breakthrough uterine bleeding still occurs, patients can be treated with depot medroxyprogesterone (150 mg every 3 months) until bleeding no longer occurs.

### Bibliography

CHAPTER 44

ESTROGENS, PROGESTINS, AND THE FEMALE REPRODUCTIVE TRACT

Hall JM, McDonnell DP. The estrogen receptor β-isofrom (ER β) of the human estrogen receptor mediates ER β transcriptional activity and is a key regulator of the cellular response to estrogens and antiestrogens. Endocrinology, 1999; 140:5566–5578.

This page intentionally left blank
Testosterone and Other Androgens

In men, testosterone is the principal secreted androgen. Leydig cells synthesize the majority of testosterone by the pathways shown in Figure 45–1. In women, testosterone also is the principal androgen and is synthesized in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors androstenedione and DHEA are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone

Testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains many of the other differences between men and women. In the first trimester in utero, the fetal testes begin to secrete testosterone, the principal factor in male sexual differentiation, probably stimulated by hCG from the placenta. By the beginning of the second trimester, the serum testosterone concentration is close to that of midpuberty, about 250 ng/dL (Figure 45–2). Testosterone production then falls by the end of the second trimester, but by birth the value is again about 250 ng/dL, possibly due to stimulation of the fetal Leydig cells by LH from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at about 250 ng/dL at 2–3 months after birth and falls to less than 50 ng/dL by 6 months, where it remains until puberty. During puberty, from about 12 to 17 years of age, the serum testosterone concentration in males increases so that by early adulthood the serum testosterone concentration is 300 ng/dL to 800 ng/dL in men, compared to 30 ng/dL to 50 ng/dL in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

Luteinizing hormone, secreted by the pituitary gonadotropes (see Chapter 42), is the principal stimulus of testosterone secretion in men, perhaps potentiated by FSH, also secreted by gonadotropes. The secretion of LH by gonadotropes is positively regulated by hypothalamic GnRH; testosterone directly inhibits LH secretion in a negative-feedback loop. LH is secreted in pulses, which occur approximately every 2 h and are greater in magnitude in the morning (Crowley et al., 1985). The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Testosterone secretion is likewise pulsatile and diurnal, the highest plasma concentrations occurring at about 8 AM and the lowest at about 8 PM. The morning peaks diminish as men age. SHBG binds about 40% of circulating testosterone with high affinity, rendering the bound hormone unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving about 2% unbound or free. In women, LH stimulates the corpus luteum (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, estradiol and progesterone, not testosterone, are the principal inhibitors of LH secretion in women.

Metabolism of Testosterone to Active and Inactive Compounds

Testosterone has many different effects in tissues, both directly and through its metabolism to dihydrotestosterone and estradiol (Figure 45–3). The enzyme 5α-reductase catalyzes the conversion of...
testosterone to dihydrotestosterone. Dihydrotestosterone binds to the AR with higher affinity than testosterone and activates gene expression more efficiently. Two forms of 5α-reductase have been identified: type I, which is found predominantly in nongenital skin, liver, and bone; and type II, which is found predominantly in urogenital tissue in men and genital skin in men and women. The enzyme complex aromatase, present in many tissues, catalyzes the conversion of testosterone to estradiol. This conversion accounts for about 85% of circulating estradiol in men; the remainder is secreted directly by the testes (MacDonald et al., 1979). Hepatic metabolism converts testosterone to the biologically inactive compounds androsterone and etiocholanolone (see Figure 45–3). Dihydrotestosterone is metabolized to androsterone, androstanedione, and androstanediol.

Physiological and Pharmacological Effects of Androgens

Testosterone is the principal circulating androgen in men. At least three mechanisms contribute to the varied effects of testosterone:

- direct binding to the AR;
- conversion in certain tissues to dihydrotestosterone, which also binds to the AR; and
- conversion to estradiol, which binds to the estrogen receptor (Figure 45–4).

Effects That Occur Via the Androgen Receptor

Testosterone and dihydrotestosterone act as androgens via a single AR, a member of the nuclear receptor superfamily designated as NR3A. The AR has an amino-terminal domain that contains a polyglutamine side-chain cleavage 

-β-hydroxysteroid dehydrogenase (DHEA)
-dehydroepiandrosterone
-androstanediol
-progesterone
-17α-hydroxylation
-17, 20 lyase
repeat of variable length is unique to the AR; a shorter length appears to increase the receptor’s activity.

In the absence of a ligand, the AR is located in the cytoplasm associated with a heat shock protein complex. When testosterone or dihydrotestosterone binds to the ligand-binding domain, the AR dissociates from the heat shock protein complex, dimerizes, and translocates to the nucleus. The dimer then binds via the DNA-binding domains to androgen response elements on certain responsive genes. The ligand-receptor complex recruits coactivators and acts as a transcription factor complex, stimulating or repressing expression of those genes (Agoulnik and Weigel, 2008).

Mutations in the hormone or DNA-binding regions of the AR result in resistance to the action of testosterone, beginning in utero (McPhaul and Griffin, 1999); as a consequence, male sexual differentiation and pubertal development are incomplete. Other AR mutations occur in patients with spinal and bulbar muscular atrophy, known as Kennedy disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the molecule (Walcott and Merry, 2002). The result is very mild androgen resistance, manifest principally by gynecomastia, and progressively severe motor neuron atrophy (Dejager et al., 2002). The mechanism by which the neuronal atrophy occurs is unknown. Other mutations in AR may explain why metastatic prostate cancer often regresses initially in response to androgen deprivation treatment, but then becomes unresponsive to continued deprivation. AR continues to be expressed in androgen-independent prostate cancer, and its signaling remains active. The ligand-independent signaling may result from mutations in the AR gene or changes in AR coregulatory proteins. In some patients resistant to standard androgen deprivation therapy, the tumor responds to further depletion of androgens by inhibitors of adrenal androgen synthesis, such as abiraterone.

**Effects That Occur Via the Estrogen Receptor**

Certain effects of testosterone are mediated by its conversion to estradiol, catalyzed by CYP19 (aromatase). In rare cases in males deficient in CYP19 or the estrogen receptor, the epiphses do not fuse, and long-bone growth continues indefinitely; moreover, such patients are osteoporotic. Administration of estradiol corrects the bone abnormalities in patients with aromatase deficiency but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone expresses the AR (Colvard et al., 1989), testosterone also may have an effect on bone via the AR. Administration of estradiol to a male with CYP19 deficiency can increase libido, suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol (Smith et al., 1994).

**Effects of Androgens at Different Stages of Life**

**In Utero**

When the fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby Wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, pubertal

---

**Figure 45–3** Metabolism of testosterone to its major active and inactive metabolites.

**Figure 45–4** Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.
and seminal vesicles. In the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia. The increase in testosterone at the end of gestation may result in further phallic growth.

**Infancy**
The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

**Puberty**
Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes. The increase in testosterone production by Leydig cells and the effect of FSH on the Sertoli cells stimulate the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously, and the changes in most of them occur gradually during the course of several years. The phallic enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow; initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Muscle mass and strength, especially of the shoulder girdle, increase, and subcutaneous fat decreases. Epiphysial bone growth accelerates, resulting in the pubertal growth spurt, but epiphysial maturation leads eventually to slowing and then cessation of growth. Bone also becomes thicker. Erythrocytosis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops. Other changes may result from the increase in testosterone during puberty; men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

**Adulthood**
The serum testosterone concentration and the characteristics of the adult man are maintained largely during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples or at the vertex. Two other conditions are of great medical significance. One is benign prostatic hyperplasia, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5α-reductase II within prostatic cells (Wilson, 1980). The other change is the development of prostate cancer. Although no direct evidence suggests that testosterone causes the disease, prostate cancer depends on androgen stimulation. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action at the receptor.

**Senescence**
As men age, the serum testosterone concentration gradually declines (see Figure 43–2), and the SHBG concentration gradually increases, so that by age 80, the total testosterone concentration is about 80% and the free testosterone is about 40% of those at age 20 (Harman et al., 2001). This fall in serum testosterone could contribute to several other changes that occur with increasing age in men, including decreases in energy, libido, muscle mass and strength, and bone mineral density, as well as increased fat mass and fractures. Androgen deprivation also leads to insulin resistance, truncal obesity, and abnormal serum lipids, as observed in patients with metastatic prostate cancer receiving this treatment (see also Chapter 68).

### Consequences of Androgen Deficiency

The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.

### During Fetal Development
Testosterone deficiency in a male fetus during the first trimester in utero causes incomplete sexual differentiation. Complete deficiency of testosterone secretion results in entirely female external genitalia. Testosterone deficiency at this stage of development also leads to failure of the Wolffian ducts to differentiate into the male internal genitalia, but the Müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete Müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally, but its action is diminished because of an abnormality of the AR or of the 5α-reductase. Abnormalities of the AR can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization in utero and result only in impaired spermatogenesis in adulthood (McPhaul and Griffin, 1999). Abnormal 5α-reductase results in incomplete virilization of the external genitalia in utero but normal development of the male internal genitalia, which requires only testosterone (Wilson et al., 1993). Testosterone deficiency during the third trimester impairs phallic growth. The result, microphallus, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH secretion or action. In addition, with testosterone deficiency, the testes fail to descend into the scrotum; this condition, cryptorchidism, occurs commonly in boys whose LH secretion is subnormal (see Chapter 42).

### Before Completion of Puberty
When a boy can secrete testosterone normally in utero but loses the capacity to do so before the anticipated age of puberty, the result is failure to complete puberty. All of the pubertal changes previously described, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue, called gynecomastia.

### After Completion of Puberty
When testosterone secretion becomes impaired after puberty (e.g., castration or antiandrogen treatment), regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. A clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably can be detected by dual-energy absorptiometry within 2 years, but an increase in fracture incidence would not be likely to occur for many years. A loss of sexual hair takes many years.

### In Women
Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) may result in the loss of effects associated with libido, energy, muscle mass and strength, and bone mineral density.

### Therapeutic Androgen Preparations
Ingestion of testosterone is not an effective means of replacing testosterone deficiency due to the rapid hepatic catabolism. Most pharmaceutical preparations of androgens, therefore, are designed to bypass hepatic catabolism of testosterone.
HORMONES AND HORMONE ANTAGONISTS

SECTION V

Testosterone Esters

Esterifying a fatty acid to the 17α-hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthate (heptanoate) or cypionate (cyclopentylpropionate) (Table 45–1), is dissolved in oil and administered intramuscularly every 1–2 weeks to hypogonadal men, the ester hydrolyzes in vivo and results in serum testosterone concentrations that range from higher than normal in the first few days after the injection to low normal just before the next injection (Figure 45–5). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone, when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic catabolism. Testosterone undecanoate in oil also can be injected and produces stable serum testosterone concentrations for 2 months.

Alkylated Androgens

Several decades ago, chemists found that adding an alkyl group to the 17α position of testosterone retards its hepatic catabolism. Consequently, 17α-alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone and cause hepatotoxicity, whereas native testosterone does not. Some 17α-alkylated androgens show greater anabolic effects than androgenic effects compared to native testosterone in laboratory tests in rats; however, these “anabolic” steroids, so favored by athletes to illicitly improve performance, have not been convincingly demonstrated to have such a differential effect in human beings. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2009; FDA, 2016).

Transdermal Delivery Systems

To avoid the “first-pass” inactivation of testosterone by the liver, chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. Available preparations include gels applied to the skin or nasal mucosa, a transdermal patch, and a buccal tablet (see Figure 45–5).

Selective Androgen Receptor Modulators

Selective estrogen receptor modulators have been developed (see Chapter 44). Are selective AR modulators possible that exhibit desirable effects of testosterone in some tissues (such as muscle and bone) without the undesirable effects in other tissues, such as prostate? Nonsteroidal...
molecules with these properties have been developed and have been tested in humans, but none has yet been effective.

**Therapeutic Uses of Androgens**

**Male Hypogonadism**

The best established indication for administration of androgens is testosterone deficiency in men. Any of the testosterone preparations or testosterone esters described can be used to treat testosterone deficiency.

**Monitoring for Efficacy**

The goal of administering testosterone to a hypogonadal man is to mimic as closely as possible the normal serum concentration (see Figure 45–5). Therefore, measuring the serum testosterone concentration during treatment is the most important aspect of monitoring testosterone treatment for efficacy. With testosterone gels, the serum testosterone concentration is relatively constant from one application to the next (Swerdloff et al., 2000). When the enanthate or cypionate ester of testosterone is administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in adult men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years (Snyder et al., 2000).

**Monitoring for Deleterious Effects**

Testosterone administered by itself as a transdermal preparation has no "side effects" (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17α-alkylated androgens, do have undesirable effects even when dosages are targeted at physiological replacement. Some of these undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins.

Replacement of physiological levels of testosterone occasionally may have undesirable effects in the presence of concomitant illnesses. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these conditions.

When a man is more than 40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer. The principal adverse effects of the 17α-alkylated androgens are hepatic, including cholestasis and, uncommonly, peliosis hepatis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. The 17α-alkylated androgens, especially in large amounts, may lower serum HDL cholesterol.

**Monitoring at the Anticipated Time of Puberty**

Testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth hormone status of the boy being treated must be considered. Boys who are short because of growth hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

**Male Senescence**

Serum testosterone levels decrease as men age, and the parallels between the consequences of aging and those of hypogonadism due to pituitary or testicular disease, such as decreases in muscle mass and strength, sexual function, bone density, and hemoglobin, suggest the possibility that the decrease in testosterone with aging may contribute to these changes of aging. Several studies demonstrated that testosterone treatment of older men with low testosterone increased their muscle mass and decreased their fat mass. A new study of 788 men 65 years or older with low testosterone concentrations demonstrated that testosterone treatment, compared to placebo, for 1 year improved sexual function, mood, and depressive symptoms (Snyder et al., 2016).

No studies to date have been large enough to determine if testosterone treatment of older men will increase the risk of prostate cancer, urinary tract symptoms, or heart disease. The FDA, however, has become sufficiently concerned about the possible risk of cardiovascular disease, based on epidemiologic studies and small clinical trials, that it has required a label change for testosterone preparations to indicate that they are approved only for men with "classical hypogonadism," meaning hypogonadism due to discernible pituitary or testicular disease (Nguyen et al., 2015).

**Female Hypogonadism**

Few data exist regarding whether increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido, energy, muscle mass and strength, or bone mineral density. In a study of women with low serum testosterone concentrations due to panhypopituitarism, increasing the testosterone concentration to normal was associated with small increases in bone mineral density, fat-free mass, and sexual function compared to placebo (Miller et al., 2006).

**Enhancement of Athletic Performance**

Some athletes take drugs, including androgens, in an attempt to improve their performance. Because androgens for this purpose usually are taken surreptitiously, information about their possible effects is not as complete as that for androgens taken for treatment of male hypogonadism. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2009 and 2016).

**Kinds of Androgens Used**

Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When such use by athletes began more than 30 years ago, 17α-alkylated androgens and other compounds (the so-called anabolic steroids) that were thought to have greater anabolic effects than androgen effects relative to testosterone were used most commonly. Because these compounds can be detected readily by organizations that govern athletic competitions, other agents that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as androstenedione and DHEA, also have increased in popularity recently because they are treated as nutritional supplements and thus are not regulated by athletic organizations. A new development in use of androgens by athletes is THG, a potent androgen that appears to have been designed and synthesized to avoid detection by antidoping laboratories on the basis of its novel structure and rapid catabolism.
generally effective. One exception is in the treatment of muscle wasting. Testosterone, because of its anabolic effects, has been used in attempts to augment muscle mass, especially in athletes who take anabolic steroids with a low C17-α-alkyl substitution. The advantage of exogenous testosterone is that it is easy to give and relatively inexpensive. However, the disadvantage is that some athletes may take too much testosterone, which results in masculinization of women and girls, who are at risk for premature closure of the epiphyses and stunting of linear growth. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth. The few controlled studies of the effects of pharmacological doses of androgens do suggest a dose-dependent effect of testosterone on muscle strength that acts synergistically with exercise (Bhasin et al., 1996). In one controlled study, 43 normal young men were randomized to one of four groups: strength training with or without 600 mg of testosterone enanthate once a week (more than six times the replacement dose) or no exercise with or without testosterone. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men who exercised simultaneously experienced even greater increases (Bhasin et al., 1996). In another study, normal young men were treated with a GnRH analogue to reduce endogenous testosterone secretion severely and, in a random blinded fashion, weekly doses of testosterone enanthate from 25 to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin et al., 2001). In contrast, in a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. The treatment also did not increase the mean serum testosterone concentration (King et al., 1999).

**Side Effects**

All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis. When administered in high doses, androgens that can be converted to estrogens, such as testosterone itself, cause gynecomastia. Androgens whose A ring has been modified so that it cannot be aromatized, such as danazol, do not cause gynecomastia even in high doses. The 17α-alkylated androgens are the only androgens that cause hepatotoxicity. These androgens, when administered in high doses, affect serum lipid concentrations, specifically to decrease HDL cholesterol and increase LDL cholesterol. Women and children experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

**Detection**

An androgen other than testosterone can be detected by gas chromatography-mass spectrometry if the athlete is still taking it when tested. Exogenous testosterone itself can be detected by one of two methods. One is the T/E ratio, the ratio of testosterone glucuronide to its endogenous epimer, epitestosterone glucuronide, in urine. Administration of exogenous testosterone suppresses secretion of both testosterone and epitestosterone and replaces them with only testosterone, so the T/E ratio is higher than normal. This technique is limited, however, by heterozygosity in the UDP-glucuronosyl transferase that converts testosterone to testosterone glucuronide. An athlete who has a deletion of one or both copies of the gene coding for this enzyme and who takes exogenous testosterone will have a much lower T/E ratio than one who has both copies (Schulze et al., 2008).

A second technique for detecting administration of exogenous testosterone employs gas chromatography-combustion-isotope ratio mass spectrometry to detect the presence of 13C and 12C compounds. Urinary androgens and estrogens with a low 13C/12C ratio are likely to have originated from pharmaceutical sources as opposed to endogenous physiological sources (Aguilera et al., 2001).

**Catabolic and Wasting States**

Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with AIDS, which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin et al., 2000).

**Angioedema**

Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it. The 17α-alkylated androgens (e.g., stanozolol, danazol) stimulate hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes. Alternatively, concentrated C1-esterase inhibitor derived from human plasma may be used for protection in patients with hereditary angioedema.

**Blood Dyscrasias**

Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens, such as danazol, still are used occasionally as adjunctive treatment of hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

**Antiandrogens**

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be antiandrogens and now are used intentionally for this indication. See Chapter 68 for a more detailed discussion of androgen deprivation therapy for prostate cancer.

**Inhibitors of Testosterone Secretion**

Some antifungal drugs of the imidazole family, such as ketoconazole (see Chapter 61), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis, but sometimes are employed in cases of glucocorticoid excess (see Chapter 46).

**Inhibitors of Androgen Action**

These drugs inhibit the binding of androgens to the AR or inhibit 5α-reductase.

**Androgen Receptor Antagonists**

Androgens are blocked by competitive antagonists of the AR. These drugs inhibit the binding of androgens to the AR or inhibit 5α-reductase. Androgens, such as danazol, still are used occasionally as adjunctive treatment of hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

**Spironolactone.** Spironolactone (see Chapter 25) is an inhibitor of aldosterone that also is a weak inhibitor of the AR and a weak inhibitor of testosterone synthesis. When the agent is used to treat fluid retention or hypertension in men, gynecomastia is a common side effect. In part because of this adverse effect, the selective mineralocorticoid receptor antagonist eplerenone was developed. Spironolactone can be used in women to treat hirsutism.

**Blood Dyscrasias**

Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens, such as danazol, still are used occasionally as adjunctive treatment of hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

**Antiandrogens**

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be antiandrogens and now are used intentionally for this indication. See Chapter 68 for a more detailed discussion of androgen deprivation therapy for prostate cancer.

**Inhibitors of Testosterone Secretion**

Some antifungal drugs of the imidazole family, such as ketoconazole (see Chapter 61), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis, but sometimes are employed in cases of glucocorticoid excess (see Chapter 46).

**Inhibitors of Androgen Action**

These drugs inhibit the binding of androgens to the AR or inhibit 5α-reductase.

**Androgen Receptor Antagonists**

Androgens are blocked by competitive antagonists of the AR. These drugs inhibit the binding of androgens to the AR or inhibit 5α-reductase. Androgens, such as danazol, still are used occasionally as adjunctive treatment of hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.
Erectile Signaling and Erectile Dysfunction

Nitric oxide acts by binding and activating sGC, which catalyzes the production of cyclic GMP from cellular GTP. Cyclic GMP is a second messenger that activates PKG, leading to phosphorylation of contractile proteins and ion channels to decrease the concentration of intracellular Ca\(^{2+}\), resulting in smooth muscle relaxation and increased blood flow to corpora cavernosa. PDE5 degrades cyclic GMP; thus, erectile dysfunction can be improved by drugs that retard the degradation of cyclic GMP by inhibiting PDE5 (Goldstein et al., 1998) (Figure 45–6).

PDE5 Inhibitors

Available inhibitors of PDE5 include sildenafil, vardenafil, tadalafil, and avanafil. All of these agents compete for cyclic GMP binding at the site of cyclic GMP hydrolysis on PDE5. PDE5 inhibitors are also used in treating pulmonary arterial hypertension (Chapter 31).

ADME

Table 45–2 summarizes a number of pharmacokinetic properties of the available PDE5 inhibitors. These agents are adequately absorbed orally, widely distributed, and act fairly quickly (within ~ 30 min). Their affinities, time to onset, and half-lives differ somewhat, giving patients options for onset and duration of effect. The drugs are cleared by hepatic CYP3A4, with minor contributions by CYP2C9 (20% for sildenafil). Excretion of metabolites is largely via the feces, with urinary excretion playing a secondary role in excretion of tadalafil (36%) (Mehrotra et al., 2007).

Clinical Use

All of these agents produce satisfactory results in most patients. The starting dose recommendations vary, and patients should start at the lowest recommended dose. This is especially important in patients over 65 years.

Adverse Effects, Precautions

Adverse effects are similar but not identical across this drug class owing to their similar mechanism of action but their differing specificities toward PDE5 compared to other PDE isoforms. Common complaints are headache, flushing, dyspepsia, nasal congestion, dizziness, and back pain. Some patients using sildenafil or vardenafil may notice blurred vision and a
blue-green tinting of vision, referable to inhibition of retinal PDE6, which is involved in phototransduction (see Figure 69-9).

Concomitant administration of potent CYP3A inducers (e.g., bosentan) will generally cause substantial decreases in plasma levels of drugs in this class. CYP3A inhibitors (e.g., protease inhibitors used in human immunodeficiency virus therapy, erythromycin, and cimetidine) inhibit metabolism of PDE5 inhibitors, thereby prolonging the half-lives and elevating blood levels of these agents. Consistent with their mechanism of action, potentiation of cyclic GMP signaling, PDE5 inhibitors potentiate the hypotensive effects of nitrate vasodilators, producing dangerously low blood pressures. Thus, the administration of PDE5 inhibitors to patients receiving organic nitrates is contraindicated. The patient’s underlying cardiovascular status and concurrent use of hypotensive agents (e.g., nitrates, α adrenergic antagonists) must be considered prior to use of this class of drugs. Priapism (erection lasting longer than 4 h) induced by PDE5 inhibitors runs the risk of ischemic damage to the cavernosal smooth muscle and sinusaloidal epithelium and requires medical attention.

Developing Therapies for Erectile Dysfunction

In addition to use of PDE5 inhibitors, alternative routes for regulating smooth muscle tone in the corpus cavernosum are being actively explored. For example, direct activators of guanylyl cyclase are now available (e.g., riociguat). Local inhibition of arginase may enhance NO production in cases where arginine, the substrate for NO synthase, limits NO production (Caldwell et al., 2015). Rho A and Rho kinase are highly expressed in penile smooth muscle, where Rho kinase phosphorylates and inhibits the regulatory subunit of myosin light chain phosphatase and helps to maintain a tonic contracted state of the cavernosal smooth muscle (an antierectile state), thereby promoting maintenance of the flaccid state. In experimental preparations, inhibitors of Rho kinase (e.g., fasudil) will elicit penile erection (Sopko et al., 2014). Mirabegron, a β3 adrenergic agonist used in treatment of overactive bladder, relaxes isolated muscle strips from human and rodent corpus cavernosum (Gur et al., 2016), and H2S has proerectile activity mediated by its effect on a large-conductance Ca++-activated K+ in cavernosal smooth muscle (Jupiter et al., 2015).

**Bibliography**

This page intentionally left blank
The major physiological and pharmacological effects of ACTH result from the increase in circulating levels of adrenocortical steroids that ACTH causes. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because corticosteroids mimic the therapeutic effects of ACTH, synthetic steroids generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are used at physiological doses as replacement therapy when endogenous production is impaired. Glucocorticoids potently suppress inflammation, and their use in inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because glucocorticoids exert effects on almost every organ system, their administration and withdrawal may be complicated by serious side effects. Therefore, the decision to institute therapy with systemic glucocorticoids always requires careful consideration of the relative risks and benefits in each patient.

**Corticotropin**

Human ACTH, a peptide of 39 amino acids, is synthesized as part of a larger precursor protein, POMC, and is derived from the precursor by proteolytic cleavage at dibasic residues by the serine endoprotease, prohormone convertase 1 (also known as prohormone convertase 3) (Figure 46–1). Other biologically important peptides, including endorphins, lipotropins, and the MSHs, also are produced by proteolytic processing of the same POMC precursor (see Chapter 20 and Takahashi and Mizusawa, 2013).

The actions of ACTH and the other melanocortins derived from POMC are mediated by their specific interactions with five MCR subtypes (MC1–MC5) comprising a subfamily of GPCRs (Cone, 2006; Montero-Melendez, 2015). The well-known effects of MSH on pigmentation result from interactions with MC1R on melanocytes. ACTH, which is identical to α-MSH in its first 13 amino acids, exerts its effects on the adrenal cortex through MC2R. The affinity of ACTH for MC2R is much lower than for MC1R; however, under pathological conditions in which ACTH levels are persistently elevated, such as primary adrenal insufficiency, ACTH also can signal through MC1R. β-MSH and possibly other melanocortins, acting via MC5R and MC6R in the hypothalamus, play a role in regulating appetite and body weight. The role of MC5R is less well defined, but studies in rodents suggest

**Inhibitors of Steroidogenesis**

**Glucocorticoid Antagonist**

Addison described fatal outcomes in patients with adrenal destruction in a presentation to the South London Medical Society in 1849. These studies were soon extended when Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It later was shown that the adrenal cortex, rather than the medulla, was essential for survival in these ablation experiments, and that the adrenal cortex regulated both carbohydrate metabolism and fluid and electrolyte balance. The isolation and identification of the adrenal steroids by Reichenstein and Kendall and the effects of these compounds on carbohydrate metabolism (hence the term glucocorticoids) culminated with the synthesis of cortisone, the first pharmacologically effective glucocorticoid to become readily available. Subsequently, Tait and colleagues isolated and characterized a distinct corticosteroid, aldosterone, which potentially affected fluid and electrolyte balance and therefore was termed a mineralocorticoid. The isolation of distinct corticosteroids that regulated carbohydrate metabolism or fluid and electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors (reviewed by Miller, 2013).

Studies of adrenocortical steroids also played a key part in delineating the role of the anterior pituitary in endocrine function. As early as 1912, Cushing described patients with hypercorticism, and he later recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was further shown to be essential for maintaining the structural integrity and steroidogenic capacity of the inner cortical zones. Harris established the role of the hypothalamus in pituitary control and postulated that a soluble factor produced by the hypothalamus activated ACTH release. These investigations culminated with the determination of the structure of CRH, a hypothalamic peptide that, together with AVP, regulates secretion of ACTH from the pituitary (Miller, 2013).

Shortly after synthetic cortisone became available, Hench and colleagues demonstrated its dramatic effect in the treatment of rheumatoid arthritis, setting the stage for the clinical use of corticosteroids in a wide variety of diseases, as discussed in this chapter.
Abbreviations

ACh: acetylcholine
ACTH: corticotropin (formerly adrenocorticotropic hormone)
AngII: angiotensin II
AP-1: activator protein 1
ATPase: adenosine triphosphatase
AVP: arginine vasopressin
CAH: congenital adrenal hyperplasia
CBG: corticosteroid-binding globulin
CIRCI: critical illness–related cortisol insufficiency
CNS: central nervous system
COX: cyclooxygenase
CRF: corticotropin-releasing factor (CRF
1, CRF
2)
CRH: corticotropin-releasing hormone
CYP: cytochrome P450
CYP11A1: cholesterol side-chain cleavage enzyme
CYP11B1: aldosterone synthase
CYP11B2: 11ß-hydroxylase
CYP17: 17α-hydroxylase
CYP19: aromatase
CYP21: steroid 21-hydroxylase
DHEA: dehydroepiandrosterone
ELAM-1: endothelial-leukocyte adhesion molecule 1
FDA: Food and Drug Administration
GM-CSF: granulocyte-macrophage colony-stimulating factor
GR: glucocorticoid receptor
GRE: glucocorticoid-response element
HPA: hypothalamic-pituitary-adrenal
3β-HSD: 3β-hydroxysteroid dehydrogenase
11β-HSD1: 11β-hydroxysteroid dehydrogenase (type 1)
11β-HSD2: 11β-hydroxysteroid dehydrogenase (type 2)
HSP70: 70-kDa heat shock protein
HSP90: 90-kDa heat shock protein
ICAM-1: intercellular adhesion molecule 1
Ig: immunoglobulin
IL: interleukin
IP: 56-kDa immunophilin
IP
3: inositol trisphosphate
LPH: lipotropin
LT: leukotriene
MCR: melanocortin receptor
MR: mineralocorticoid receptor
mRNA: messenger RNA
MSH: melanocyte-stimulating hormone
NF-κB: nuclear factor kappa B
NOS: nitric oxide synthase
PG: prostaglandin
PK: protein kinase
PLC: phospholipase C
POMC: pro-opiomelanocortin
RANK: receptor for activating NF-κB
SSTR: somatostatin receptor
TNF: tumor necrosis factor

Roles in exocrine secretion and pheromone-related aggressive behavior (Morgan and Cone, 2006).

Actions on the Adrenal Cortex

Acting via MC
2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor DHEA. The adrenal cortex histologically and functionally can be separated into three zones (Figure 46–2) that produce different steroid products under different regulatory influences:

- The outer zona glomerulosa secretes the mineralocorticoid aldosterone.
- The middle zona fasciculata secretes the glucocorticoid cortisol.
- The inner zona reticularis secretes DHEA and its sulfated derivative DHEA-S (plasma concentration 1000 times that of DHEA). DHEA sulfatase converts DHEA-S to DHEA in the periphery.

Cells of the outer zone have receptors for both ACTH and AngII and express aldosterone synthase (CYP11B2), the enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by AngII and extracellular K
+ (see Chapter 25) and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. With persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed ACTH escape).

Figure 46–1 Processing of POMC to ACTH. POMC is converted to ACTH and other peptides in the anterior pituitary. The boxes within the ACTH structure indicate regions important for steroidalogenic activity (residues 6–10) and binding to the ACTH receptor (15–18). α-MSH also derives from the POMC precursor and contains the first 13 residues of ACTH.

Figure 46–2 The three anatomically and functionally distinct compartments of the adrenal cortex. The major functional compartments of the adrenal cortex are shown, along with the steroidalogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiological regulators of steroid production: AngII and K
+ for the zona glomerulosa and ACTH for the zona fasciculata. The physiological regulator(s) of DHEA production by the zona reticularis are not known, although ACTH acutely increases DHEA biosynthesis.
Cells of the zona fasciculata have fewer receptors for AngII and express steroid 17α-hydroxylase (CYP17) and 11β-hydroxylase (CYP11B1), enzymes that catalyze the production of glucocorticoids. In the zona reticularis, CYP17 carries out an additional C17–20 lyase reaction that converts C21 corticosteroids to C19 androgen precursors.

In the absence of the anterior pituitary and ACTH stimulation, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired. Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hyper trophy and hyperplasia of the inner zones of the adrenal cortex, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis.

**Mechanism of Action**

Corticotropin stimulates the synthesis and release of adrenocortical hormones by increasing de novo biosynthesis. ACTH, binding to MC2R, activates the Gs–adenyl cyclase–cyclic AMP–PKA pathway. Cyclic AMP is the second messenger for most effects of ACTH on steroidogenesis.

Temporally, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, largely reflects an increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes.

A number of transcriptional regulators participate in the induction of the steroidogenic enzymes by ACTH. Among these is the nuclear receptor NR5A1 (steroidogenic factor 1), a transcription factor required for the development of the adrenal cortex and for the expression of most of the steroidogenic enzymes (Schimmer and White, 2010). Pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 46–3. The rate-limiting step in steroid hormone production is the translocation of cholesterol across mitochondrial membranes by the steroid acute regulatory protein. Cholesterol is then converted to pregnenolone by the side-chain cleavage enzyme, CYP11A1, which represents the first enzymatic step in steroid hormone biosynthesis (Miller and Auckus, 2011). Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily (see Chapter 6). To ensure an adequate supply of substrate for steroidogenesis, the adrenal cortex uses multiple sources of cholesterol, including circulating cholesterol and cholesterol esters taken up via the low-density lipoprotein and high-density lipoprotein receptor pathways; endogenous cholesterol liberated from cholesterol ester stores via activation of cholesterol esterases; and endogenous cholesterol from de novo biosynthesis.

**Extra-adrenal Effects of ACTH**

In large doses, ACTH causes a number of metabolic changes in adrenalectomized animals, including ketosis, lipolysis, hypoglycemia (immediately after treatment), and resistance to insulin (later after treatment). Given the large doses of ACTH required, the physiological significance of these extra-adrenal effects is questionable.

**Regulation of ACTH Secretion**

**Hypothalamic-Pituitary-Adrenal Axis**

The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes are regulated by CRH and AVP, peptide hormones released by specialized neurons of the endocrine hypothalamus into the network of portal veins bathing the anterior pituitary (Papadimitriou and Priftis, 2009). This HPA axis forms an integrated system that maintains appropriate levels of glucocorticoids (Figure 46–4). The three characteristic modes of physiologic regulation of the HPA axis are:

- *diurnal rhythm* in basal steroidogenesis
- *negative feedback regulation* by adrenal corticosteroids
- marked increases in steroidogenesis in response to stress.

Pathologic elevation of steroidogenesis is seen in Cushing disease, the ectopic ACTH syndrome, and conditions where GRs or MRs are defective.

The *diurnal rhythm* is determined by circadian clocks in the hypothalamus, suprachiasmatic nucleus, and adrenal gland itself and is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at about 8 AM. (Leliviski et al., 2015). *Negative feedback regulation* occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

Following release into the hypophyseal plexus, CRH is transported via this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotropes. On CRH binding, the CRH receptor activates the Gs–adenyl cyclase–cyclic AMP pathway within corticotropes, ultimately stimulating both ACTH biosynthesis and secretion. CRH and CRH-related peptides called urocortins also are produced at other sites, including the amygdala and hindbrain, gut, skin, adrenal gland, adipose tissue, placenta, and additional sites in the periphery. The classical CRH receptor, now designated CRF1 receptor, belongs to the class II family of GPCRs that includes receptors for calcitonin, parathyroid hormone, growth hormone–releasing hormone, secretin, glucagon, and glucagon-like peptide. A second CRH receptor, the CRF2 receptor, is distinguished from the CRF1 receptor in its binding specificities for CRH and the urocortins. The finding that the HPA axis often is altered in patients suffering from major depressive disorders illustrates the complex relationships between stress and mood and has stimulated considerable interest in the possible use of CRH antagonists in disorders such as anxiety and depression (Holboer and Ising, 2008).

**Arginine Vasopressin**

Arginine vasopressin also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. AVP is produced in the paraventricular nucleus and secreted into the pituitary portal veins from the median eminence. AVP binds to V1a receptors and activates the Gs–PLC–IP3–Ca2+ pathway to enhance the release of ACTH. In contrast with CRH, AVP does not increase ACTH synthesis.

**Negative Feedback of Glucocorticoids**

Glucocorticoids inhibit ACTH secretion via direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and via direct effects on corticotropes. The indirect inhibitory effects on CRH neurons appear to be mediated by both corticosteroid receptors in the hippocampus. At lower cortisol levels, MRs, which have higher affinity for glucocorticoids than GRs, are the major receptor species occupied. As glucocorticoid concentrations rise and saturate MRs, the GRs become increasingly occupied. Both MRs and GRs apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves GRs. In the pituitary, glucocorticoids act through GRs to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes) and delayed (requiring hours and involving changes in gene transcription mediated through GRs).

**The Stress Response**

Stress overcomes negative-feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, increased corticosteroid secretion is vital to maintain homeostasis in these settings. As discussed further in the chapter, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response.
The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways unique to the zona glomerulosa are shown in the orange box; those that occur in the inner zona fasciculata and zona reticularis are shown in the gray box. The zona reticularis does not express 3β-HSD and thus preferentially synthesizes DHEA.

**Therapeutic Uses and Diagnostic Applications of ACTH**

Corticotropin has limited utility therapeutically. All proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects. Moreover, therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. Cosyntropin, a synthetic peptide that corresponds to residues 1–24 of human ACTH, is used in testing the integrity of the HPA axis. At the considerably supraphysiological dose of 250 μg, cosyntropin maximally stimulates adrenocortical steroidogenesis. An increase in the circulating cortisol to a level greater than 18–20 μg/dL indicates a normal response. Cosyntropin may be used diagnostically in adrenal venous sampling to distinguish between unilateral and bilateral aldosterone oversecretion in primary aldosteronism.

**CRH Stimulation Test**

Ovine CRH (corticorelin) and human CRH (not available in the U.S.) are used for diagnostic testing of the HPA axis. In patients with documented ACTH-dependent hypercortisolism, CRH testing may help differentiate pituitary (i.e., Cushing disease) from ectopic sources of ACTH.

**Assays for ACTH**

Immunochemiluminescent assays that use two separate antibodies directed at distinct epitopes on the ACTH molecule now are widely used.
HORMONES AND HORMONE ANTAGONISTS

ALDOSTERONE

available. These assays increase the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemiluminescent ACTH assays also are useful in differentiating ACTH-dependent from ACTH-independent forms of hypercortisolism: High ACTH levels are seen when the hypercortisolism results from pituitary adenomas (e.g., Cushing disease) or nonpituitary tumors that secrete ACTH (e.g., the syndrome of ectopic ACTH), whereas low ACTH levels are seen in patients with excessive glucocorticoid production due to primary adrenal disorders. One problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

Absorption, Fate, and Toxicity

Corticotropin is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the t1/2 in plasma is about 15 min, primarily due to rapid enzymatic hydrolysis. Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyn tropin generally is less antigenic than native ACTH.

Adrenocortical Steroids

The adrenal cortex synthesizes two classes of steroids: the corticosteroids (glucocorticoids and mineralocorticoids; see Figure 46–3), which have 21 carbon atoms, and the androgens, which have 19 carbons (see Figure 45–3). The actions of corticosteroids historically were described as glucocorticoid (reflecting their carbohydrate metabolism–regulating activity) and mineralocorticoid (reflecting their electrolyte balance–regulating activity). In humans, cortisol is the main glucocorticoid, and aldosterone is the physiologic mineralocorticoid. Table 46–1 shows typical rates of secretion of cortisol and aldosterone, as well as their normal circulating concentrations.

Although the adrenal cortex is an important source of androgen precursors in women, patients with adrenal insufficiency can be restored to normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Adrenal androgens are not essential for survival. The sulfated derivative DHEA-S is the most highly secreted adrenal steroid; levels of DHEA and DHEA-S peak in the third decade of life and decline progressively thereafter. Moreover, patients with a number of chronic diseases have very low DHEA levels, leading some to propose that DHEA treatment might at least partly alleviate the loss of libido, the decline in cognitive function, the decreased sense of well-being, and other adverse physiological consequences of aging. However, studies on the benefits of addition of DHEA to the standard replacement regimen in women with adrenal insufficiency have been inconclusive. Despite the absence of definitive data, DHEA is widely used as an over-the-counter nutritional supplement for its alleged health benefits.

Physiological Functions and Pharmacological Effects

Corticosteroids have numerous effects, which include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist stressful and noxious stimuli and environmental changes. In the absence of adequate secretion of corticosteroids from the adrenal cortex, stresses such as infection, trauma, and extremes in temperature can be fatal.

The actions of corticosteroids are related to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Conversely, in the absence of glucocorticoids, epinephrine and NE have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed permissive and most likely reflect steroid-induced changes in protein synthesis, which, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are termed either mineralocorticoids or glucocorticoids, according to their relative potencies in Na+ retention and effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis). In general, the potencies of steroids on glucose metabolism closely parallel their potencies as anti-inflammatory agents. The effects on Na+ retention and the carbohydrate/anti-inflammatory actions are not closely related and reflect selective actions at distinct receptors. As noted in further discussion (see structure–activity relationships and Table 46–3), some steroid derivatives provide relative selectivity as stimulants of Na+ retention or anti-inflammatory effects.

General Mechanisms for Corticosteroid Effects

Corticosteroids bind to specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby changing the levels and array of proteins synthesized by the various target tissues (Figure 46–5). Many effects of corticosteroids are not immediate but become apparent after several hours; clinically, one often but not invariably sees a delay before beneficial effects of corticosteroid therapy become

manifest. Although corticosteroids predominantly act by increasing gene transcription, there are examples in which glucocorticoids decrease gene transcription. In addition, corticosteroids exert their immediate effects by nongenomic mechanisms, usually via classical GRs or MRs (Prigent et al., 2004).

**Glucocorticoid Receptors.** The receptors for corticosteroids are members of the nuclear receptor family of transcription factors. GRs (also called NR3C1, nuclear receptor subfamily 3, group C, member 1) reside predominantly in the cytoplasm in an inactive form complexed with other proteins. Steroid binding results in receptor activation and translocation to the nucleus (see Figure 46–5). Several GR isoforms result from alternative RNA splicing and from translation initiation at alternative sites. Of these, GRs is the prototypical glucocorticoid-responsive isoform. A second major GR isoform, GRβ, is a truncated, dominant, negative variant that lacks 35 amino acids at the C terminal and is unable to bind glucocorticoids or activate gene expression. Multiple polymorphisms in the human GR are associated with differences in GR function and have been linked to glucocorticoid insensitivity (Vandeveyver et al., 2014).

**Regulation of Gene Expression by Glucocorticoids.** After ligand binding, GRs dissociate from their associated proteins and translocate to the nucleus. There, they interact with specific DNA sequences called GREs, which provide specificity in terms of induction of gene transcription by glucocorticoids. Genes can be activated or inhibited by GR-GRE interactions. The mechanisms whereby GR activate transcription are complex and not completely understood, but they involve interaction with transcriptional coactivators and with proteins that make up the basal transcription apparatus. In an example of transcriptional inhibition GRs inhibit transcription of POMC by a direct interaction with a GRE in the POMC promoter, thereby contributing to the negative-feedback regulation of the HPA axis. Other genes negatively regulated by glucocorticoids include genes for COX-2, inducible NOS (NOS2), and inflammatory cytokines. Some inhibitory effects of glucocorticoids, such as downregulation of expression of genes encoding a number of cytokines, collagenase, and stromelysin, have been linked to protein-protein interactions between the GRs and other transcription factors (e.g., NF-kB and AP-1) rather than to negative effects of the GRs at specific GREs. Such protein–protein interactions and their consequent negative effects on gene expression appear to contribute significantly to the anti-inflammatory and immunosuppressive effects of the glucocorticoids (De Bosscher et al., 2003).

**Regulation of Gene Expression by Mineralocorticoids.** Like GRs, the MR also is a ligand–activated transcription factor and binds to a very similar hormone-responsive element. MRs also associate with HSP90 and GREs to activate the transcription of discrete sets of genes in target tissues. GRs and MRs differ in their ability to inhibit AP-1–mediated gene activation and, in terms of gene transcription, by their differential recruitment of other transcription factors. In addition, GRs are essentially ubiquitous, whereas MRs are expressed in epithelial tissues involved in electrolyte transport (i.e., the kidney, colon, salivary glands, and sweat glands) and in some nonepithelial tissues (e.g., hippocampus, heart, vasculature, and adipose tissue).

Aldosterone exerts its effects on Na+ and K+ homeostasis primarily via its actions on the principal cells of the distal renal tubules and collecting ducts, whereas effects on H+ secretion largely are exerted in the intercalated cells. The binding of aldosterone to the MRs in the kidney initiates a sequence of events that includes the rapid induction of serin-and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na+ channels in the apical membrane. Thereafter, increased Na+ influx stimulates the Na+, K+-ATPase in the basolateral membrane. In addition to these rapid genomic actions, aldosterone increases the synthesis of the individual components of these membrane proteins as part of a more delayed effect.

**Receptor-Independent Mechanism for Corticosteroid Specificity.** Aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) bind the MRs with equal affinity. In epithelial cells of the kidney, colon, and salivary glands, aldosterone specifically activates MRs in the face of much higher circulating levels of glucocorticoids due to the coexpression of the type 2 isozyme of 11β-HSD2. This enzyme metabolizes glucocorticoids such as cortisol to inactive 11-keto derivatives such as cortisone (Figure 46–6). Aldosterone escapes this inactivation and maintains mineralocorticoid activity because its predominant physiological form is the hemiacetal derivative that is resistant to 11β-HSD action (Figure 46–7). In the absence of 11β-HSD2, as occurs in the inherited disease syndrome of apparent mineralocorticoid excess, the MR is activated by cortisol, leading to severe
Hormones and Hormone Antagonists, a component of licorice implicated in licorice-induced hypertension.

Carbohydrate and Protein Metabolism

Glucocorticoids markedly affect carbohydrate and protein metabolism, which can be viewed as protecting glucose-dependent tissues (e.g., the brain and heart) from starvation. Glucocorticoids stimulate the liver to form glucose from amino acids and glycerol and to store glucose as glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Through their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in susceptible patients.

Lipid Metabolism

Two effects of glucocorticoids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in hypercortisolism, such as Cushing syndrome. In this setting, there is increased fat in the back of the neck ("buffalo hump"), face ("moon facies"), and supraclavicular area, coupled with a loss of fat in the extremities. The other is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration.

Electrolyte and Water Balance

Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na⁺ from the tubular fluid; they also increase the urinary excretion of K⁺ and H⁺. These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that characterize of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na⁺ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na⁺ concentration, normal or low plasma K⁺, and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na⁺ wasting and contraction of the extracellular fluid volume, hypotension, hyperkalemia, and acidosis. Chronically, hyperaldosteronism causes hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain the glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney. In addition to their effects on monovalent cations and water, glucocorticoids exert multiple effects on Ca²⁺ metabolism, lowering Ca²⁺ uptake from the gut and increasing Ca²⁺ excretion by the kidney, collectively leading to decreased total body Ca²⁺ stores.

Cardiovascular System

The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na⁺ retention, as is evident in primary aldosteronism. MR activation has direct effects on the heart and vessel walls; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis appears to result from direct mineralocorticoid actions in the heart (Zannad and Radaicheau, 2005). The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced responsiveness to vasoconstrictors such as NE and AngII, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

Skeletal Muscle

Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, secondary to either glucocorticoid therapy or endogenous hypercortisolism, causes skeletal muscle wasting. This effect, steroid myopathy, accounts in part for weakness and fatigue in patients with glucocorticoid excess.

CNS

Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability. Patients with adrenal insufficiency exhibit a diverse array of neurological manifestations, including apathy, depression, irritability, and even psychosis. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as mania, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing syndrome.

Formed Elements of Blood

Glucocorticoids exert minor effects on hemoglobin and the erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing syndrome and of normochromic, normocytic anemia.
in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish erythrocyte destruction.

Corticosteroids also affect circulating white blood cells. Addison disease is associated with an increased mass of lymphoid tissue and lymphocytosis; in contrast, Cushing syndrome is characterized by lymphopenia and a decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4–6 h; this effect persists for 24 h and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and decreased adherence to vascular walls. Finally, glucocorticoids are effective in the treatment of certain lymphoid malignancies, possibly related to the capacity of glucocorticoids to activate apoptosis.

**Anti-inflammatory and Immunosuppressive Actions**

In addition to their effects on lymphocyte number, glucocorticoids profoundly alter the immune responses of lymphocytes. These effects are important facets of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Although the use of glucocorticoids as anti-inflammatory agents does not address the underlying cause of the disease, the suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents.

Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (see Chapter 70), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (see Chapter 35). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. Glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemotactic factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of pro-inflammatory cytokines, as well as COX-2 and NOS2. Some of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 46–2.

Among the pro-inflammatory cytokines, IL-1, IL-6, and TNF-α stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1 stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. The increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites as discussed previously. Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Turnbull and Rivier, 1999).

**ADME**

**Absorption**

Hydrocortisone and numerous congeners, including the synthetic analogues, are orally effective. Certain water-soluble esters of hydrocortisone and its synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in systemic or targeted body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action. Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

**Distribution, Metabolism, and Excretion**

After absorption, 90% or more of cortisol in plasma is reversibly bound to protein under normal circumstances. In most tissues, only the fraction of corticosteroid that is unbound is active and can enter cells. Two plasma proteins account for almost all of the steroid-binding capacity: CBG (also called transcortin) and albumin. CBG is an α globulin secreted by the liver that has high affinity for steroids (dissociation constant of ~1 nM) but relatively low total binding capacity, whereas albumin, also produced by the liver, has a relatively large binding capacity but low affinity (estimated dissociation constant of ~1 mM). In tissues with prolonged capillary transit time (e.g., liver, spleen), steroid dissociates from albumin. At high steroid concentrations, the capacity of CBG binding is exceeded, and a slightly greater fraction of the steroid exists in the free state. CBG has relatively high affinity for cortisol and some of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these last steroids are found in the free form. A special state of physiological hypercortisolism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase several-fold; the physiological significance of these changes remains to be established.

The aldosterone levels also rise 3- to 10-fold in pregnancy, reflecting the activity of the elevated progesterone plasma levels as an MR antagonist. Because progesterone is also a GR antagonist, it may contribute to the elevated levels of cortisol.

As a general rule, the metabolism of steroid hormones involves sequential additions of O or H atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond (Figure 46–3) occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxy derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring-reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronate by enzymatic reactions that take place in the liver and, to a lesser extent, in the kidney. The resultant sulfate esters and glucuronides are water soluble and are excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto group, such as cortisol and prednisone, must be enzymatically reduced to the corresponding 11β-hydroxy derivative before they are biologically active (Figure 46–6). The type 1 isozyme of 11β-HSD (11β-HSD1) catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., hydrocortisone or prednisolone rather than cortisol or prednisone). Such settings include individuals with severe hepatic failure and patients with the very rare condition of cortisol reductase deficiency.

**Structure-Activity Relationships**

Chemical modifications of the cortisol molecule have generated derivatives with greater separation of glucocorticoid and mineralocorticoid activity (Table 46–3); for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used. In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these are summarized in Table 46–4. None of these currently available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism or from suppressive effects on the HPA axis. Estimates of Na⁺-retaining and anti-inflammatory potencies of representative steroids are listed in Table 46–3. Some steroids that are classified predominantly as glucocorticoids (e.g., cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency, the mineralocorticoid effects of these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na⁺ retention but has only minimal effects on carbohydrate metabolism. Even at levels that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

**Toxicity of Adrenocortical Steroids**

Two categories of toxic effects result from the therapeutic use of glucocorticoids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life threatening and require a careful assessment of the risks and benefits in each patient.

**Withdrawal Therapy**

The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. Several other complications are associated with steroid withdrawal. The most severe, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to full recovery can be a year or longer.

Protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment have been proposed. Patients who have received supraphysiological doses of glucocorticoids for a period of 2–4 weeks within the preceding year should be considered to have some degree of HPA impairment. A characteristic glucocorticoid withdrawal syndrome consists of fever, myalgia, arthralgia, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted. Finally, *pseudotumor cerebri*, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

**Continued Use of Supraphysiological Glucocorticoid Doses**

Besides the consequences that result from the suppression of the HPA axis, a number of other complications result from prolonged therapy with glucocorticoids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, peptic ulcers, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habits of steroid overdose, including fat redistribution, striae, and ecchymoses.

**Fluid and Electrolyte Handling.** Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis and hypertension, particularly

Notes: Topical preparations include agents for application to skin or mucous membranes in creams, solutions, ointments, gels, pastes (for oral lesions), and aerosols; ophthalmic preparations include solutions, suspensions, and ointments. Inhalation preparations include agents for nasal or oral inhalation.

Fludrocortisone acetate is intended for use as a mineralocorticoid.

---

in patients with primary hyperaldosteronism secondary to an adrenal adenoma or in patients treated with potent mineralocorticoids. Similarly, hypertension is a relatively common manifestation of exogenous glucocorticoid administration, even in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

### Metabolic Changes

The effects of glucocorticoids on intermediary metabolism were described previously. Hyperglycemia with glycosuria usually can be managed with diet or insulin, and its occurrence should not be a major factor in the decision to continue corticosteroid therapy or to initiate therapy in diabetic patients.

### Immune Responses

Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections of some consequence, glucocorticoids should be administered only if absolutely necessary and concomitantly with appropriate and effective antimicrobial or antifungal therapy.

### Possible Risk of Peptic Ulcers

There is considerable debate about the association between peptic ulcers and glucocorticoid therapy. The possible onset of hemorrhage and perforation in these ulcers and their insidious onset make peptic ulcers a serious therapeutic problem (Chapter 49). Prudence suggests vigilance for peptic ulcer formation in patients receiving therapy with corticosteroids, especially if administered concomitantly with aspirin or coxibs.

### Myopathy

Myopathy, characterized by weakness of proximal limb muscles, can occur in patients taking large doses of corticosteroids and also is part of the clinical picture in patients with endogenous Cushing syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (Chapter 40); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

### Behavioral Changes

Behavioral disturbances are common after administration of corticosteroids and in patients who have Cushing syndrome secondary to endogenous hypercorticism; these disturbances may take many forms, including nervousness, insomnia, changes in mood or psyche, and overt psychosis.

### Cataracts

Cataracts are a well-established complication of glucocorticoid therapy and are related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of opacities, and the cataracts may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at prednisone doses of 10–15 mg/d or greater should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

### Osteoporosis

Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of both genders and all ages and is related to dosage and duration of therapy. About 30%–50% of all patients who receive chronic glucocorticoid therapy ultimately will develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and the cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormones, diminished GI absorption of Ca\(^{2+}\), and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption by osteoclasts via changes in the production of osteoprotegerin and RANK ligand (see Chapter 48). In addition, glucocorticoid inhibition of intestinal Ca\(^{2+}\) uptake may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The initiation of glucocorticoid therapy at 5 mg/d or more of prednisone (or its equivalent) for 3 months or longer is an indication for bone densitometry to detect abnormalities in trabecular bone. Because bone loss associated with glucocorticoids predominantly occurs within the first...
6 months of therapy, densitometric evaluation of the lumbar spine and hip, along with prophylactic measures, should be initiated. Most authorities advocate maintaining a Ca\(^{2+}\) intake of 1500 mg/d by diet plus Ca\(^{2+}\) supplementation and vitamin D intake of 800 IU/d, assuming that these measures do not increase urinary calcium excretion above the normal range. An important advance in the prevention of glucocorticoid-related osteoporosis is the successful use of bisphosphonates (e.g., risedronate and zoledronic acid), which have been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 44 and 48.

**Osteonecrosis.** Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of time. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

**Regulation of Growth and Development.** Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by (off-label) treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. In experimental animals, antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. The actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in late gestation and in the neonatal period (e.g., production of pulmonary surfactant and induction of hepatic gluconeogenic enzymes); those actions notwithstanding, antenatal steroids may lead to subtle abnormalities in fetal development. Babies born to women receiving large doses of corticosteroids during pregnancy should be monitored for signs of adrenal insufficiency and appropriate therapy initiated, if necessary.

**Therapeutic Uses and Diagnostic Applications in Endocrine Diseases**

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the optimal dose to achieve a given therapeutic effect must be determined by trial and error and periodic reevaluation as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond 1 week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. When glucocorticoids are to be given over long periods, the dose, determined empirically, must be the lowest that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate tapering the glucocorticoid dose once the initial benefit of therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent accurate observations of the patient.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient. Long courses of therapy at high doses should be reserved for life-threatening disease.

To diminish HPA axis suppression, the intermediate-acting steroid preparations (e.g., prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoid is employed for patients who obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1–1.5 g/d IV of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders, such as acute exacerbations of multiple sclerosis, acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis.

**Replacement Therapy for Adrenal Insufficiency**

Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in developing countries. Other causes include adrenoleukodystrophy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, AIDS, inherited disorders of the steroidogenic enzymes, and X-linked adrenal leukodystrophy. Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

**Acute Adrenal Insufficiency.** The life-threatening disease of acute adrenal insufficiency is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hypernatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus and sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic NaCl solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiac function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload, such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone should be given by continuous infusion at a rate of 50–100 mg every 8 h, a dose that confers sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6–8 h. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency. For the initial management of unconfirmed acute adrenal insufficiency, 4 mg of dexamethasone sodium phosphate can be substituted for hydrocortisone; dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin [ACTH] stimulation test). Failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency.
**Chronic Adrenal Insufficiency.** Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis but with lesser severity. These patients require daily treatment with corticosteroids. The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency, the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overreplacement may cause manifestations of Cushing syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed but should be less than 100 pg/mL (22 pmol/L).

Traditional replacement regimens have used hydrocortisone in doses of 20–30 mg/d; however, some authorities use lower doses of 15–20 mg/d based on estimates of daily rates of cortisol production (Table 46–1). Cortisone acetate, which is inactive until converted to cortisol by 11β-HSD1, also has been used in doses ranging from 25 to 37.5 mg/d. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; fludrocortisone acetate generally is used in doses of 0.05–0.2 mg/d. In secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate because the zona glomerulosa, which makes mineralocorticoids, is usually intact.

When initiating treatment in patients with panhypopituitarism, administer glucocorticoids before initiating treatment with thyroid hormone because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol. Dexamethasone and prednisone also have been used as chronic replacement therapy; however, careful monitoring for hypercortisolism is required due to their increased potency and longer durations of action.

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., phenytoin, barbiturates, or rifampin) or who suffer the stress of infection or surgery. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo surgery. In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/d; a standard regimen is hydrocortisone 100 mg parenterally every 8 h. Following surgery, the dose is halved each day until it is reduced to routine maintenance levels.

**Congenital Adrenal Hyperplasia.** CAH is a group of genetic disorders in which there is a deficiency in the activity of one of several enzymes required for the biosynthesis of glucocorticoids. The impaired production of cortisol and the consequent lack of negative-feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. CAH includes a spectrum of disorders for which precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient. In about 90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylase reaction (see Figure 46–3). Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess, such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH are born with virilized external genitalia (female pseudohermaphroditism) that result from elevated production of adrenal androgen precursors at critical stages of sexual differentiation in utero and often require reconstructive genital surgery. Some medical centers have experimented with dexamethasone administration in utero with success; however, this approach is highly controversial because of concerns regarding abnormal behavioral development after prenatal exposure to glucocorticoids (Miller and Witchel, 2013). Males appear normal at birth and later may have precocious development of secondary sexual characteristics (male precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses. Some patients with classical CAH are unable to conserve Na+ normally and thus are called “salt wasters.”

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is about 0.6 mg/kg daily in two or three divided doses. The mineralocorticoid used is fludrocortisone acetate (0.05–0.2 mg/d). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurs in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

**Diagnostic Applications of Dexamethasone**

In addition to its therapeutic uses, dexamethasone is used as a first-line agent to diagnose hypercortisolism and to differentiate among the different causes of Cushing syndrome (Arnaldi et al., 2003). To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cortisol biosynthesis, an overnight dexamethasone suppression test has been devised. Patients are given 1 mg of dexamethasone orally at 11 PM, and cortisol is measured at 8 AM the following morning. Suppression of plasma cortisol to less than 1.8 μg/dL suggests strongly that the patient does not have Cushing syndrome. Drugs such as barbiturates that enhance dexamethasone metabolism or drugs (estrogens) or conditions (pregnancy) that increase the concentrations of CBG can interfere with suppression and compromise the test.

The formal dexamethasone suppression test is used in the differential diagnosis of biochemically documented Cushing syndrome. Following determination of baseline cortisol levels for 48 h, dexamethasone (0.5 mg every 6 h) is administered orally for 48 h. This dose markedly suppresses cortisol levels in normal subjects, including those who have nonspecific elevations of cortisol due to obesity or stress, but it does not suppress levels in patients with Cushing syndrome. In the high-dose phase of the test, dexamethasone is administered orally at 2 mg every 6 h for 48 h. Patients with pituitary-dependent Cushing syndrome (i.e., Cushing disease) generally respond with decreased cortisol levels. In contrast, patients with ectopic production of ACTH or with adenocortical tumors generally do not exhibit decreased cortisol levels. Despite these generalities, dexamethasone may suppress cortisol levels in some patients with ectopic ACTH production, particularly with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administration to make this distinction.

**Therapeutic Uses in Nonendocrine Diseases**

There are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed next illustrate the principles governing glucocorticoid use in selected diseases. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. Approximate doses of a representative glucocorticoid (e.g., prednisone) are provided.

**Rheumatic Disorders**

Glucocorticoids are used widely in the treatment of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory...
rhematic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg/d in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by the clinical picture.

Glucocorticoids are often used in conjunction with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents.

Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Intermediate-acting glucocorticoids, such as prednisone and prednisolone, are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with their chronic use, glucocorticoids are used as stabilizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory drugs. In this case, glucocorticoids provide relief until other, slower-acting antirheumatic drugs (e.g., methotrexate or agents targeted at TNF) take effect. A typical starting dose is 5–10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20–40 mg/d of prednisone or equivalent), with rapid taper thereafter. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5–20 mg of the very long-acting triamcinolone acetonide or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to use a glucocorticoid that does not require bioactivation (e.g., prednisolone rather than prednisone) and to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

**Renal Diseases**

Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1–2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6–8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2–3 weeks in 85% of patients, and more than 95% of patients enter remission within 3 months. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8–10 weeks (e.g., prednisone 120 mg every other day), followed by a 1- to 2-month period of tapering.

**Allergic Diseases**

The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine. The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone 125 mg IV every 6 h or equivalent) are appropriate. For allergic rhinitis, many experts recommend intranasal steroids.

**Pulmonary Diseases**

The use of glucocorticoids in bronchial asthma and other pulmonary diseases is discussed in Chapter 40. Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely. Betamethasone (12 mg IM every 24 h for two doses) or dexamethasone (6 mg IM every 12 h for four doses) is administered to women with definitive signs of premature labor between 26 and 34 weeks of gestation. For women still at risk of preterm birth 7 or more days after receiving the initial glucocorticoid dose, a meta-analysis of 10 randomized clinical trials involving over 4730 women and 5700 infants showed that a second course of treatment reduced the risk of respiratory distress syndrome and serious neonatal morbidity without adverse effects in infants followed for 2 to 3 years after (McKinlay et al., 2012).

**Infectious Diseases**

Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One example is in patients with AIDS with *Pneumocystis carinii* pneumonia and moderate-to-severe hypoxia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children 2 months of age or older.

**Ocular Diseases**

Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival sac. For diseases of the posterior segment, intraocular injection or systemic administration is required. These uses of glucocorticoids are discussed in Chapter 69.

**Skin Diseases**

Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Efficacy is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatological disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/d of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Chapter 70 presents the dermatologic uses of glucocorticoids.

**Gastrointestinal Diseases**

Patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn disease) who fail to respond to more conservative management (i.e., rest, diet, and sulfasalazine) may benefit from glucocorticoids; steroids are most useful for acute exacerbations of chronic disease. The dose in these settings is usually 40 mg/d of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Chapter 70 presents the dermatologic uses of glucocorticoids.

**Hepatic Diseases**

The use of corticosteroids in hepatic disease has been controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis; as many as 80% of patients show histological remission when treated with prednisone (40–60 mg daily initially, with tapering to a maintenance dose of 7.5–10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent meta-analyses did not support a beneficial role of corticosteroids. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

**Malignancies**

Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects, most commonly as a component of combination therapy (see Chapters 67 and 68). They also are used to manage chemotherapy-induced nausea and
vomiting (Table 50–5) and to reduce hypersensitivity reactions and fluid retention associated with taxane chemotherapy (Chapter 66).

Cerebral Edema
Corticosteroids at very high doses (e.g., dexamethasone 4–16 mg every 6 h) are commonly used in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic.

Miscellaneous Uses
Sarcoidosis. Corticosteroids are indicated therapy for patients with debilitating symptoms or life-threatening forms of sarcoidosis. Patients with severe pulmonary involvement are treated with 20–40 mg/d of prednisone, or an equivalent dose of alternative steroids, to induce remission. Higher doses may be required for other forms of this disease. Maintenance doses may be as low as 5 mg/d of prednisone. All patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate are at increased risk of secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should be considered for prophylactic antituberculosis therapy.

Thrombocytopenia. In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1–1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed high-dose glucocorticoid therapy.

Autoimmune Destruction of Erythrocytes. Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive Coombs test) are treated with prednisone (1 mg/kg/d). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

Organ Transplantation. In organ transplantation, high doses of prednisone (50–100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (see Chapter 35). For some solid-organ transplants (e.g., pancreas), protocols that either withdraw corticosteroids early after transplantation or that avoid them completely have become more common (Niederhaus et al., 2013).

Spinal Cord Injury. Large doses of methylprednisolone sodium succinate (30 mg/kg initially followed by an infusion of 5.4 mg/kg/h for 23 h) are a treatment option for patients with acute spinal cord injury. Although, multicenter controlled trials have demonstrated decreases in neurological defects in patients with acute spinal cord injury treated within 8 h of injury (Bracken, 2012), concerns regarding statistical analysis, reproducibility of data, and potential side effects of treatment have caused some experts to advocate against use of methylprednisolone in this setting (Hurlbert et al., 2013).

**Inhibitors of ACTH Secretion and the Biosynthesis and Actions of Adrenocortical Steroids**

Hypercortisolism with its attendant morbidity and mortality is most frequently caused by corticotroph adenomas that overproduce ACTH (Cushing disease) or by adrenocortical tumors or bilateral hyperplasias that overproduce cortisol (Cushing syndrome). Less frequently, hypercortisolism may result from adrenocortical carcinomas or ectopic ACTH- or CRH-producing tumors. Although surgery is the treatment of choice, it is not always effective, and adjunct therapy with pharmacological inhibitors becomes necessary. In these settings, inhibitors of ACTH secretion and of adrenal steroidogenesis are clinically useful. All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient’s HPA axis must be carefully monitored. Most of the inhibitors discussed here are considered in detail in other chapters; mineralocorticoid antagonists are not considered here but are discussed in Chapter 25.

**Inhibitors of ACTH Secretion**

**Pasireotide**
Pasireotide is a somatostatin analogue that is an agonist at four of the five subtypes of SSTR, with especially high affinity for SSTR5. Through these interactions, pasireotide effectively inhibits growth hormone secretion and is used in the treatment of acromegaly (Chapter 42). Pasireotide also inhibits ACTH secretion and reduces the circulating levels of cortisol in patients with ACTH-producing pituitary tumors; the agent is FDA-approved for use in those patients with Cushing disease who are not candidates for surgery or who have recurrent disease. At subcutaneous doses of 0.6 or 0.9 mg twice daily, pasireotide reduces urinary free cortisol levels by at least 50% in approximately half the treated patients; depending on the dose, cortisol levels reach the normal range in 15%–26% of patients. Treatment improves signs and symptoms of hypercortisolism, including blood pressure, low-density lipoprotein cholesterol, and body mass index. Common adverse effects include hyperglycemia, gallstones, and transient GI discomfort (Colao et al., 2012).

**Cabergoline**
Cabergoline is a potent long-acting dopamine D2 receptor agonist used primarily to treat hyperprolactinemia (Chapter 42). Cabergoline also inhibits ACTH secretion from corticotroph tumors, which are often D2 receptor positive. Several small studies have shown that 37% of patients with recurrent Cushing disease achieve normal levels of free urinary cortisol when treated with cabergoline. The FDA has not yet approved cabergoline for this use.

**Inhibitors of Steroidogenesis**

**Ketoconazole**
Ketoconazole is an antifungal agent (see Chapter 61). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because it inhibits the activity of CYP17 (17α-hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is an effective inhibitor of steroid hormone biosynthesis in patients with hypercortisolism (although the FDA has not approved use for this indication). In most cases, a dosage regimen of 600–800 mg/d (in two divided doses) is required, and some patients may require up to 1200 mg/d (in two or three doses). Side effects include hepatic dysfunction with the possibility of severe hepatic injury. The potential of ketoconazole to alter drug transport and metabolism by inhibiting P-glycoprotein and CYP3A4 can lead to serious drug interactions (see Chapters 5 and 6).

**Metyrapone**
Metyrapone is a relatively selective inhibitor of CYP11B1 and thus inhibits the conversion of 11-deoxycorticisol to cortisol, thereby reducing cortisol production and elevating precursor levels (e.g., 11-deoxycortisosterone and its precursor 11-deoxycorticosterone). Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycorticosterone and 11-deoxycorticisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol and 11-deoxycorticisol are measured at 8 AM the next morning. A plasma cortisol less than 8 μg/dL validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycorticisol level less than 7 μg/dL is highly suggestive of impaired HPA function.

Metyrapone has been used off label to treat the hypercortisolism resulting from either adrenal neoplasms or tumors ectopically producing ACTH. Maximal suppression of steroidogenesis requires doses of 4 g/d. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500–750 mg three...
or four times daily is employed. The use of metyrapone in the treatment of Cushing syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycortisol/11-deoxycorticosterone. Other side effects include nausea, headache, sedation, and rash.

**Etomidate**

Etomidate, a substituted imidazole used primarily as an anesthetic agent and sedative, inhibits cortisol secretion at subhypnotic doses primarily by inhibiting CYP11B1 activity. Etomidate has been used off label to treat hypercortisolism when rapid control is required in a patient who cannot take medication by the oral route. Etomidate is administered as a bolus of 0.03 mg/kg intravenously, followed by an infusion of 0.1 mg/kg/h to a maximum of 0.3 mg/kg/h (Biller et al., 2008).

**Mitotane**

Mitotane is an adrenocorticolytic agent used to treat inoperable adrenocortical carcinoma. Its cytolytic action is due to its metabolic conversion to a reactive acyl chloride by adrenal mitochondrial CYPs and subsequent reactivity with cellular proteins. It also inhibits CYP11A1 (cholesterol side-chain cleavage enzyme), thereby reducing steroid synthesis. Initial doses range from 2 to 6 g/d administered orally in three or four divided doses. The maintenance dose is 9–10 g/d in three or four divided doses. The maximal dose can be as high as 16 g/d, if tolerated. Its onset of action takes weeks to months, and GI disturbances and ataxia are its major toxicities. See Chapter 66 for the structure of mitotane and additional details on its use.

### Glucocorticoid Antagonist

**Mifepristone**

Mifepristone (RU-486), is a progesterone receptor antagonist used to terminate early pregnancy (see Chapter 44). At higher doses, mifepristone also inhibits the GRs, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its capacity to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in a small number of patients with hypercortisolism. Mifepristone has been granted orphan drug status in the U.S. for the treatment of hyperglycemia secondary to endogenous Cushing syndrome in patients who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery.

<tr>
<td><strong>Replacement Therapy</strong></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
| Hydrocortisone/cortisone | Primary and secondary chronic adrenal insufficiency | - Hydrocortisone is the synthetic equivalent of cortisol.  
- Daily oral dose of hydrocortisone is 20–30 mg, preferably as divided doses.  
- Although nonphysiologic glucocorticoids are sometimes used, hydrocortisone or cortisone is preferred for replacement therapy.  
- **Tip:** Two-thirds of dose in the morning, one-third of dose in the evening. |
| Hydrocortisone, other glucocorticoids | Acute adrenal insufficiency  
Critical illness-related cortisol insufficiency (CIRCI) | - CIRCI reflects inadequate cortisol production or may occur with abrupt cessation of administered glucocorticoids.  
- High-dose intravenous hydrocortisone (50–100 mg/6 h) or a constant infusion of 10 mg/h is needed.  
- An alternative is prednisone at 1 mg/kg/d. |
| Fludrocortisone (9α-fluorocortisol) | Mineralocorticoid replacement | - Doses of 0.05–0.2 mg/d.  
- Lower dose is used initially and is titrated upward as required by blood pressure, plasma renin levels, and response to upright posture.  
- Fludrocortisone has a t½ > 24 h so divided doses are not necessary. |
| **Anti-inflammatory Agents: Systemic** | | |
| Prednisolone, methylprednisolone  
Dexamethasone, budesonide  
Others | Across the spectrum of inflammatory disease  
Preterm (24–34 weeks) delivery | - Initial high-dose tapering to low dose in short-course therapy.  
- In early therapy—insomnia, weight gain, emotional lability  
- With high-dose/long-term therapy: psychosis, increased susceptibility to infection, osteoporosis, osteonecrosis, myopathy, HPA axis suppression.  
- On cessation of therapy: acute hypocortisolism.  
- **Tip:** Constant vigilance. |
| **Anti-inflammatory Agents: Topical** | | |
| Betamethasone  
Hydrocortisone  
Budesonide  
Dexamethasone  
Triamcinolone acetonide | Dermatitis, pemphigus, atopic dermatitis, vitiligo, psoriasis, etc. | - Fluorinated steroids have better skin penetration than hydrocortisone.  
- Effects are magnified by occlusive dressings.  
- Local adverse events: atrophy, striae, and exacerbation of skin infection.  
- **Tip:** Skin-lightening cosmetics include corticosteroids and may produce serious systemic adverse events. |

**Bibliography**

Diabetes mellitus is a spectrum of metabolic disorders arising from myriad pathogenic mechanisms, all resulting in hyperglycemia. Both genetic and environmental factors contribute to its pathogenesis, which involves insufficient insulin secretion, reduced responsiveness to endogenous or exogenous insulin, increased glucose production, or abnormalities in fat and protein metabolism. The resulting hyperglycemia may lead to both acute symptoms and metabolic abnormalities. Major sources of the morbidity of diabetes are the chronic complications that arise from prolonged hyperglycemia, including retinopathy, neuropathy, nephropathy, and cardiovascular disease. These chronic complications can be mitigated in many patients by sustained control of the blood glucose and treatment of comorbidities such as hypertension and dyslipidemia (Nathan, 2014; Orchard et al., 2015). There are now a wide variety of treatment options for hyperglycemia that target different processes involved in glucose regulation or dysregulation (Nathan, 2015).

Physiology of Glucose Homeostasis

Regulation of Blood Glucose

The maintenance of glucose homeostasis, termed glucose tolerance, is a highly developed systemic process involving the integration of several major organs (Figure 47–1). Although the actions of insulin are of central importance, webs of interorgan communication via other hormones, nerves, local factors, and substrates also play vital roles. The pancreatic β cell is central in this homeostatic process, adjusting the amount of insulin secreted very precisely to promote glucose uptake after meals and to regulate glucose output from the liver during fasting.

In the fasting state (Figure 47–1A), the fuel demands of the body are met by the oxidation of fatty acids. The brain does not effectively use fatty acids to meet energy needs and in the fasting state requires glucose for normal function; glucose requirements are about 2 mg/kg/min in adult humans, largely to supply the CNS with an energy source. Fasting glucose requirements are primarily provided by the liver. Liver glycogen stores provide some of this glucose; conversion of lactate, alanine, and glycerol into glucose accounts for the remainder. The dominant regulation of hepatic glycogenolysis and gluconeogenesis is controlled by the pancreatic islet hormones insulin and glucagon. Insulin inhibits hepatic glucose production, and the decline of circulating insulin concentrations in the postabsorptive state (fasting) is permissive for higher rates of glucose output. Glucagon maintains blood glucose concentrations at physiological levels in the absence of exogenous carbohydrate (overnight and in between meals) by stimulating gluconeogenesis and glycogenolysis by the liver. Insulin secretion is stimulated by food ingestion, nutrient absorption, and elevated blood glucose, and insulin promotes glucose, lipid, and protein anabolism (Figure 47–1B). The centrality of insulin in glucose metabolism is emphasized by the fact that all the forms of human diabetes have as a root cause some abnormality of insulin secretion or action.

Pancreatic β cell function is primarily controlled by plasma glucose concentrations. Elevations of blood glucose are necessary for insulin release above basal levels, and other stimuli are relatively ineffective when plasma glucose is in the fasting range (4.4–5.5 mM or 80–100 mg%). These other stimuli include nutrient substrates, insulinotropic hormones released from the GI tract, and autonomic neural pathways. Neural stimuli cause some increase of insulin secretion prior to food consumption. Neural stimulation of insulin secretion occurs throughout the meal and contributes significantly to glucose tolerance. Arrival of nutrient chyme to the intestine leads to the release of insulinotropic peptides from specialized endocrine cells in the intestinal mucosa. GIP and GLP-1, together termed incretins, are the essential gut hormones contributing to glucose tolerance. They are secreted in proportion to the nutrient load ingested and relay this information to the islet as part of a feedback mechanism that allows an insulin response appropriate to meal size. Insulin secretion rates in healthy humans are highest in the early digestive phase of meals, preceding and limiting the peak in blood glucose. This pattern of premonitory insulin secretion is an essential feature of normal glucose tolerance. Mimicking this pattern is one of the key challenges for successful insulin therapy in diabetic patients.
Elevated circulating insulin concentrations lower glucose in blood by inhibiting hepatic glucose production (HGP) and stimulating the uptake and metabolism of glucose by muscle and adipose tissue. Production of glucose is inhibited half-maximally by an insulin concentration of about 120 pmol/L, whereas glucose utilization is stimulated half-maximally at about 300 pmol/L. Some of the effects of insulin on the liver occur rapidly, within the first 20 min of meal ingestion, whereas stimulation of peripheral glucose uptake may require up to an hour to reach significant rates. Insulin has potent effects to reduce lipolysis from adipocytes, primarily through the inhibition of hormone-sensitive lipase; insulin also increases lipid storage by promoting lipoprotein-lipase synthesis and adipocyte glucose uptake. In muscle and other tissues, insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation.

The limited glycogen stores in skeletal muscle are mobilized at the onset of physical activity, but most of the glucose support for exercise comes from hepatic gluconeogenesis. The dominant regulation of hepatic glucose production during exercise comes from EPI and NE. The catecholamines stimulate glycogenolysis and gluconeogenesis, inhibit insulin secretion, and enhance release of glucagon, all contributing to increased hepatic glucose output. In addition, catecholamines promote lipolysis, freeing fatty acids for oxidation in exercising muscle and glyceraldehyde 3-phosphate dehydrogenase (GPDH) to D-glyceraldehyde 3-phosphate, and stimulating the Glut-1 transporter for glucose uptake by muscle and adipose tissue. Glucagon, epinephrine, and glucagon-like peptide-1 (GLP-1) and its analogs stimulate glycogenolysis and gluconeogenesis, and inhibit insulin secretion.

## Pancreatic Islet Physiology and Insulin Secretion

The pancreatic islet comprises 1%–2% of the pancreatic volume. The pancreatic islet is a highly vascularized, highly innervated miniorgan containing five endocrine cell types: α cells that secrete glucagon, β cells that secrete insulin, δ cells that secrete SST, PP cells that secrete pancreatic polypeptide, and ε cells that secrete ghrelin.

Insulin is initially synthesized as a single polypeptide chain, proinsulin (110 amino acids), which is processed first to proinsulin and then to insulin and C-peptide (Figure 47–2). This complex and highly regulated process involves the Golgi complex, the endoplasmic reticulum, and the secretory granules of the β cell. Secretory granules are critical in the cleavage and processing of the prohormone to the final secretion products, insulin and C-peptide, and in bringing insulin to the cell membrane for exocytosis. Equimolar quantities of insulin and C-peptide (31 amino acids) are cosecreted. Insulin has a t½ of 5–6 min due to extensive hepatic clearance. C-peptide, in contrast, with no known physiological function or receptor, has a t½ of about 30 min. The C-peptide is useful in assessment of β cell secretion and to distinguish endogenous and exogenous hyperinsulinemia (e.g., in the evaluation of insulin-induced hypoglycemia). The β cell also synthesizes and secretes IAPP or amylin, a 37–amino acid polypeptide. IAPP influences GI motility and the speed of glucose absorption. Pramlintide is an agent used in the treatment of diabetes that mimics the action of IAPP.

Insulin secretion is tightly regulated to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated interplay of various nutrients, GI hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids, fatty acids, and ketone bodies promote the secretion of insulin. Glucose is the primary insulin secretagogue, and insulin secretion is tightly coupled to the extracellular glucose concentration. Insulin secretion is much greater when the same amount of glucose is delivered orally compared to intravenously, a response termed the incretin effect and attributed to insulinotropic GI peptides. Islets are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α adrenergic receptors inhibits insulin secretion, whereas β adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α adrenergic receptors.

The molecular events controlling glucose-stimulated insulin secretion begin with the transport of glucose into the β cell via GLUT, a facilitative glucose transporter, primarily GLUT1 in human β cells (Figure 47–3). On entry into the β cell, glucose is quickly phosphorylated by GK (hexokinase I)
HORMONES AND HORMONE ANTAGONISTS

Fasting state

Prandial state

Figure 47–1  Insulin, glucagon, and glucose homeostasis. A. Fasting State—In healthy humans, plasma glucose is maintained in a range from 4.4 to 5 mM and fatty acids near 400 μM. In the absence of nutrient absorption from the GI tract, glucose is supplied primarily from the liver and fatty acids from adipose tissue. With fasting, plasma insulin levels are low, and plasma glucagon is elevated, contributing to increased hepatic glycogenolysis and gluconeogenesis; low insulin also releases adipocytes from inhibition, permitting increased lipogenesis. Most tissues oxidize primarily fatty acids during fasting, sparing glucose for use by the CNS. B. Prandial State—During feeding, nutrient absorption causes an increase in plasma glucose, resulting in release of incretins from the gut and neural stimuli that promote insulin secretion. Under the control of insulin, the liver, skeletal muscle, and adipose tissue actively take up glucose. Hepatic glucose production and lipolysis are inhibited, and total body glucose oxidation increases. The brain senses plasma glucose concentrations and provides regulatory inputs contributing to fuel homeostasis. The boldness of the arrows reflects relative intensity of action; a dashed line indicates little or no activity.

Figure 47–2  Synthesis and processing of insulin. The initial peptide, preproinsulin (110 amino acids) consists of a signal peptide (SP), B chain, C-peptide, and A chain. The SP is cleaved and S-S bonds form as the proinsulin folds. Two prohormone convertases, PC1 and PC2, cleave proinsulin into insulin, C-peptide, and two dipeptides. Insulin and C-peptide are stored in granules and cosecreted in equimolar quantities.

and the ratio of ADP/ATP. Elevated ATP inhibits an ATP-sensitive K⁺ channel (KATP channel), leading to cell membrane depolarization. This heteromeric KATP channel consists of an inward rectifying K⁺ channel (Kir6.2) and a closely associated protein known as the SUR. Mutations in the Kir6.2 channel are responsible for specific types of neonatal diabetes and hyperinsulinemic hypoglycemia. Membrane depolarization following KATP closure leads to opening of a voltage-dependent Ca²⁺ channel and increased intracellular Ca²⁺, resulting in exocytotic release of insulin from storage vesicles. These intracellular events are modulated by changes in cAMP production, amino acid metabolism, and the level of transcription factors. GPCRs for glucagon, GIP, and GLP-1 and other regulatory peptides couple to G i to stimulate adenylyl cyclase and insulin secretion; receptors for SST and α adrenergic agonists couple to Gs to reduce cellular cAMP production and secretion.

The pancreas as a cell secretes glucagon, primarily in response to hyperglycemia. Glucagon biosynthesis begins with preproglucagon, which is processed in a cell-specific fashion to several biologically active peptides, such as glucagon, GLP-1, and GLP-2 (see Figure 47–9). In general, glucagon and insulin secretion are regulated in a reciprocal fashion; that is, the agents or processes that stimulate insulin secretion inhibit glucagon secretion. Notable exceptions are arginine and SST: Arginine stimulates and SST inhibits the secretion of both hormones.

Insulin Action

The insulin receptor is expressed on virtually all mammalian cell types. Tissues that are critical for regulation of blood glucose are liver, skeletal muscle, fat (Figure 47–1), and specific regions of the brain and the pancreatic islet. The actions of insulin are anabolic, and insulin signaling is critical for promoting the uptake, use, and storage of the major nutrients: glucose, lipids, and amino acids. Insulin stimulates glycogen synthesis, lipogenesis, and protein synthesis; it also inhibits the catabolism of these compounds.
cellular level, insulin stimulates transport of substrates and ions into cells, promotes translocation of proteins between cellular compartments, regulates the action of specific enzymes, and controls gene transcription and mRNA translation. Some effects of insulin (e.g., activation of glucose and ion transport systems, phosphorylation or dephosphorylation of specific enzymes) occur within seconds or minutes; other effects (e.g., those promoting protein synthesis and regulating gene transcription and cell proliferation) manifest over minutes to hours to days. The effects of insulin on cell proliferation and differentiation occur over a longer period of time.

The Insulin Receptor

Insulin action is transmitted through a receptor tyrosine kinase that bears functional similarity to the IGF-1 receptor (Samuel and Shulman, 2016). The insulin receptor is composed of linked α/β subunit dimers that are products of a single gene; dimers linked by disulfide bonds form a transmembrane heterotetramer glycoprotein composed of two extracellular a subunits and two membrane-spanning β subunits (Figure 47–4). The number of receptors varies from 40/cell on erythrocytes to 300,000/cell on adipocytes and hepatocytes.

The α subunits inhibit the inherent tyrosine kinase activity of the β subunits. Insulin binding to the α subunits releases this inhibition and allows transphosphorylation of one β subunit by the other and autophosphorylation at specific sites from the juxtamembrane region to the intracellular tail of the receptor. Activation of the insulin receptor initiates signaling by phosphorylating a set of intracellular proteins, including the IRSs and Shc protein. These proteins interact with effectors that amplify and extend the signaling cascade.

Insulin action on glucose transport depends on the activation of PI3K. PI3K is activated by interaction with IRS proteins and generates PIP3, which regulates the localization and activity of several downstream kinases, including PKB (Akt), atypical isoforms of PKC (ς and λ/τ), and mTOR. The isoform Akt2 appears to control the downstream steps that are important for glucose uptake in skeletal muscle and adipose tissue and to regulate glucose production in the liver. Substrates of Akt2 coordinate the translocation of GLUT4 to the plasma membrane through processes involving actin remodeling and other membrane trafficking systems. Actions of small G proteins, such as Rac and TC10, have also been implicated in the actin remodeling necessary for GLUT4 translocation.

Figure 47–3  Regulation of insulin secretion from a pancreatic β cell. The pancreatic β cell in a resting state (fasting blood glucose) is hyperpolarized. Elevated plasma glucose enters the cell via GLUTs (primarily GLUT1 in humans). The resulting enhanced glucose metabolism elevates cellular ATP, which reduces K⁺ conductance through the Kᵥ₉.₃ channel; the decreased K⁺ conductance results in local membrane depolarization and activation of Ca²⁺ and Na⁺ channels; the increased Ca²⁺ stimulates exocytosis of stored insulin, using the basic mechanisms described for exocytosis of neurotransmitters (Figures 8–4 to 8–6). ACh, acting via M₁ receptors, can activate the Gₛ-PLC-IP₃-Ca²⁺-PKC pathway; incretins, also acting via GPCRs, can activate the Gₛ-AC-cAMP-PKA/EPAC2 pathway; both of these GPCR-activated pathways enhance exocytosis. Elevated cAMP also leads to inhibition of the Kᵥ₉.₃ channel, enhancing depolarization and furthering exocytosis. The depolarization/exocytosis period is limited by closure of voltage-sensitive ion channels, by export of Ca²⁺ and Na⁺, and by sequestration of Ca²⁺ within the SR by the SERCA transporter. SST₃, acting via SST2 and SST3 that couple to Gₛ, can aid in restoring the hyperpolarized state of the cell, as can α₂ agonists. The Kᵥ₉.₃ channel has SUR1 and Kir 6.2 subunits; ATP binds to and inhibits Kir 6.2; sulfonylureas and meglitinides bind to and inhibit SUR1, thereby inhibiting insulin secretion. Mitochondrial mutations and islet-enriched transcription factors can contribute to the development of diabetes. This schematic is a simplification; Rorsman and Braun (2013) have reviewed the subject in greater detail. G, G protein, with subtype indicated by subscript; AC, adenylyl cyclase; EPAC, exchange protein activated by cAMP; GLUT, GLUT1 glucose transporter; GPCR, G-protein coupled receptor; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; SST2/3, somatostatin receptors.
**Pathways of insulin signaling.** The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P indicates the phosphorylated tyrosine residue, Y) of the receptor’s β subunits and a small number of specific substrates (yellow shapes): the IRS proteins Gab-1 and Shc; within the membrane, a caveolar pool of insulin receptor phosphorolyses Cav, APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects resulting from each pathway. In the target tissues such as skeletal muscle and adipocytes, a key event is the translocation of GLUT4 from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and noncaveolar pathways. In the noncaveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP3) or an atypical form of PKC is involved. In the caveolar pathway, caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves a series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein TC10. The pathways are inactivated by specific phosphoprotein phosphatases (e.g., PTB1B). In addition to the actions shown, insulin stimulates the plasma membrane Na\(^{+}\)-K\(^{+}\) pump activity and a net accumulation of K\(^{+}\) in the cell. APS, adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CAV, caveolin; CrkII, chicken tumor virus regulator of kinase II; Gab-1, Grb-2 associated binder; GLUT4, glucose transporter 4; PDK, phosphoinositide-dependent kinase; Y-P, phosphorylated tyrosine residue.

**GLUT4**

GLUT4 is expressed in insulin-responsive tissues such as skeletal muscle and adipose tissue. In the basal state, most GLUT4 resides in the intracellular space; following activation of insulin receptors, GLUT4 is shifted rapidly and in abundance to the plasma membrane (Saltiel, 2016), where it facilitates inward transport of glucose from the circulation. Insulin signaling also reduces GLUT4 endocytosis, increasing the residence time of the protein in the plasma membrane (Saltiel, 2016). Following the facilitated diffusion into cells along a concentration gradient, glucose is phosphorylated to G6P by hexokinases. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin. G6P can be isomerized to G1P and stored as glycogen (insulin enhances the activity of glycogen synthase); G6P can enter the glycolytic pathway (for ATP production) and the pentose phosphate pathway.

**Impaired glucose tolerance (IGT):** glucose level between 7.8 and 11.1 mmol/L (140 and 199 mg/dL) 120 min after ingestion of 75 g liquid glucose solution

**Diabetes mellitus** (see Table 47–1)

The American Diabetes Association (ADA) and the World Health Organization (WHO) have adopted criteria for the diagnosis of diabetes based on the fasting blood glucose, the glucose value following an oral glucose challenge, or the level of HbA\(_1c\) (or more simply, A1c; exposure of

**Pathophysiology and Diagnosis of Diabetes Mellitus**

**Glucose Homeostasis and the Diagnosis of Diabetes**

Broad categories of glucose homeostasis are defined by the fasting blood glucose or the glucose level following an oral glucose challenge. These include the following:

- Normal glucose homeostasis: fasting plasma glucose < 5.6 mmol/L (100 mg/dL)
- Impaired fasting glucose (IFG): 5.6–6.9 mmol/L (100–125 mg/dL)
- Impaired glucose tolerance (IGT): glucose level between 7.8 and 11.1 mmol/L (140 and 199 mg/dL) 120 min after ingestion of 75 g liquid glucose solution
- Diabetes mellitus

</table>

Note: In the absence of unequivocal hyperglycemia and acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

\(^a\)Random is defined as without regard to time since the last meal.

\(^b\)Fasting is defined as no caloric intake for at least 8 h.

\(^a\)The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; this test is not recommended for routine clinical use.

proteins to elevated glucose produces nonenzymatic glycation of proteins, including Hb, so the level of A1c represents a measure of the average glucose concentration to which the Hb has been exposed) (see Table 47–1). IFG and IGT portend a markedly increased risk of progressing to type 2 diabetes and are associated with increased risk of cardiovascular disease.

The four categories of diabetes include type 1 diabetes, type 2 diabetes, other forms of diabetes, and GDM (Table 47–2). Although hyperglycemia is common to all forms of diabetes, the pathogenic mechanisms leading to diabetes are quite distinct.

### Screening for Diabetes and Categories of Increased Risk of Diabetes

Many individuals with type 2 diabetes are asymptomatic at the time of diagnosis, and diabetes is often found on routine blood testing for non–glucose-related reasons. The ADA recommends widespread screening for type 2 diabetes of adults with the following features:

- Age more than 45 years, or
- Body mass index greater than 25 kg/m² (or greater than 23 kg/m² in persons of Asian descent) with one of these additional risk factors:
  - physical inactivity; hypertension; low HDL value; family history of type 2 diabetes; high-risk ethnic group (African American, Latino, Native American, Asian American, and Pacific Islander); abnormal glucose testing (IFG, IGT, A1c of 5.7%–6.4%); cardiovascular disease; features of insulin resistance; or women with polycystic ovary syndrome who have previously delivered a large infant or had GDM.

### Pathogenesis of Type 1 Diabetes

Type 1 diabetes accounts for 5%–10% of diabetes and results from autoimmune-mediated destruction of the β cells of the islet, leading to total or near-total insulin deficiency (Atkinson et al., 2014). Prior terminology included juvenile-onset diabetes mellitus or insulin-dependent diabetes mellitus. Type 1 diabetes can occur at any age. Individuals with type 1 diabetes and their families have an increased prevalence of autoimmune diseases such as Addison, Graves, and Hashimoto diseases; pernicious anemia; vitiligo; and celiac sprue. The concordance of type 1 diabetes in genetically identical twins is 40%–60%, indicating a significant genetic component. The major genetic risk (40%–50%) is conferred by HLA class II genes encoding HLA-DR and HLA-DQ. However, there likely is a critical interaction of genetics and an environmental or infectious agent. Most individuals with type 1 diabetes (about 75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population.

Genetically susceptible individuals are thought to have a normal β cell number or mass until β cell–directed autoimmune develops and β cell loss begins. The initiating or triggering stimulus for the autoimmune process is not known, but most favor exposure to viruses (enterovirus, etc.) or other ubiquitous environmental agents. The β cell destruction is likely cell mediated, and there is also evidence that infiltrating cells produce local inflammatory agents such as TNF-α, IFN-γ, and IL-1, all of which can lead to β cell death. The β cell destruction occurs over a period of months to years and when more than 80% of the β cells are destroyed, hyperglycemia ensues and the clinical diagnosis of type 1 diabetes is made. The ADA and others now recognize three stages of type 1 diabetes: 1) autoimmunity plus normal insulin secretion; 2) autoimmunity with dysglycemia; 3) autoimmunity with hyperglycemia (diabetes). Most patients report several weeks of polyuria and polydipsia, fatigue, and often abrupt and significant weight loss. Some adults with the phenotypic appearance of type 2 diabetes (obese, not insulin-requiring initially) have islet cell autoantibodies suggesting autoimmune-mediated β cell destruction and are diagnosed as having latent-autoimmune diabetes of adults (LADA).

### Pathogenesis of Type 2 Diabetes

The type 2 diabetes condition is best thought of as a heterogeneous syndrome of dysregulated glucose homeostasis associated with impaired insulin secretion and action. Overweight or obesity is a common correlate of type 2 diabetes that occurs in about 80% of affected individuals. For the vast majority of persons developing type 2 diabetes, there is no clear inciting incident; rather, the condition is thought to develop gradually over years, with progression through an identifiable prediabetic stage. Type 2 diabetes results when there is insufficient insulin action to maintain plasma glucose levels in the normal range. Insulin action is the composite effect of plasma insulin concentrations (determined by islet β cell function) and insulin sensitivity of key target tissues (liver, skeletal muscle, and adipose tissue). These sites of regulation are all impaired to variable extents in patients with type 2 diabetes (Figure 47–5). The etiology of type 2 diabetes has a strong genetic component. It is a heritable condition with a relative 4-fold increased risk of disease for persons having a diabetic parent or sibling, increasing to 6-fold if both parents have type 2 diabetes. Although more than 80 genetic loci with clear associations to type 2 diabetes have been identified through recent genome-wide association studies, the contribution of each is relatively small (Fuchsberger et al., 2016).
HORMONES AND HORMONE ANTAGONISTS

In type 2 diabetes, the sensitivity of the β cell to glucose is impaired, and there is also a loss of responsiveness to other stimuli, such as insulino-tropic GI hormones and neural signaling. This results in delayed secretion of insufficient amounts of insulin, allowing the blood glucose to rise dramatically after meals, and failure to restrain liver glucose release during fasting. The absolute mass of β cells also is reduced in patients with type 2 diabetes. Progressive reduction of β cell mass and function explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients sometimes have elevated levels of fasting insulin, a result of their higher fasting glucose levels and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the diabetic islet. Whereas healthy subjects have only 2%–4% of total circulating insulin as proinsulin, patients with type 2 diabetes can have 10%–20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin. Excessive and dysregulated glucagon secretion is another prominent feature of type 2 diabetes (D’Alessio, 2011).

Insulin Resistance

Insulin sensitivity is measured as the amount of glucose cleared from the blood in response to a fixed dose of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as insulin resistance. There is inherent variability of insulin sensitivity amongst cells, tissues, and individuals. Insulin sensitivity is affected by many factors, including age, body weight, physical activity levels, illness, and medications. Nonetheless, persons with type 2 diabetes or glucose intolerance have reduced capacity of insulin to suppress HGP and promote hepatic glucose uptake with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycogen synthesis and abnormally high fasting glucose concentrations. The liver is resistant to insulin action in type 2 diabetes, and the capacity of insulin to suppress HGP and promote hepatic glucose uptake and glycogen synthesis after meals is reduced. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in

Impaired β Cell Function

In type 2 diabetes, the sensitivity of the β cell to glucose is impaired, and there is also a loss of responsiveness to other stimuli, such as insulino-tropic GI hormones and neural signaling. This results in delayed secretion of insufficient amounts of insulin, allowing the blood glucose to rise dramatically after meals, and failure to restrain liver glucose release during fasting. The absolute mass of β cells also is reduced in patients with type 2 diabetes. Progressive reduction of β cell mass and function explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients sometimes have elevated levels of fasting insulin, a result of their higher fasting glucose levels and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the diabetic islet. Whereas healthy subjects have only 2%–4% of total circulating insulin as proinsulin, patients with type 2 diabetes can have 10%–20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin. Excessive and dysregulated glucagon secretion is another prominent feature of type 2 diabetes (D’Alessio, 2011).

Insulin Resistance

Insulin sensitivity is measured as the amount of glucose cleared from the blood in response to a fixed dose of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as insulin resistance. There is inherent variability of insulin sensitivity amongst cells, tissues, and individuals. Insulin sensitivity is affected by many factors, including age, body weight, physical activity levels, illness, and medications. Nonetheless, persons with type 2 diabetes or glucose intolerance have reduced capacity of insulin to suppress HGP and promote hepatic glucose uptake with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycogen synthesis and abnormally high fasting glucose concentrations. The liver is resistant to insulin action in type 2 diabetes, and the capacity of insulin to suppress HGP and promote hepatic glucose uptake and glycogen synthesis after meals is reduced. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in

Dysregulated Hepatic Glucose Metabolism

In type 2 diabetes, hepatic glucose output is excessive in the fasting state and inadequately suppressed after meals. Abnormal secretion of the islet hormones—insufficient insulin and excessive glucagon—accounts for a significant portion of dysregulated hepatic glucose metabolism in type 2 diabetes. Increased concentrations of glucagon, especially in conjunction with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycogenolysis and abnormally high fasting glucose concentrations. The liver is resistant to insulin action in type 2 diabetes, and the capacity of insulin to suppress HGP and promote hepatic glucose uptake and glycogen synthesis after meals is reduced. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in
Pathogenesis of Other Forms of Diabetes

Mutations in key genes involved in glucose homeostasis cause monogenic diabetes, which is inherited in an autosomal dominant fashion (Hattersley and Patel, 2017). These fall in two broad categories: diabetes onset in the immediate neonatal period (<6 months of age) and diabetes in children or adults. Some forms of neonatal diabetes are caused by mutations in SUR or its accompanying inward rectifying K+ channel or mutations in the insulin gene. Monogenic diabetes beyond the first year of life may appear clinically similar to type 1 or type 2 diabetes. In other instances, children, adolescents, and young adults may present with monogenic forms of diabetes known as MODY (maturity onset diabetes of the young). Phenotypically, these individuals are not obese or insulin resistant and may initially have only modest hyperglycemia. The most common causes are mutations in key islet-enriched transcription factors or GK (Table 47–2). Most individuals with MODY are treated similarly to those with type 2 diabetes; some may respond to a sulfonylurea.

Chronic diseases of the pancreas, such as pancreatitis or cystic fibrosis, or endocrinopathies such as acromegaly and Cushing disease (see Table 47–2) can cause diabetes. A number of medications promote hyperglycemia or lead to diabetes by impairing either insulin secretion or insulin action (Table 47–3).

Diabetes-Related Complications

Untreated diabetes can lead to severe metabolic disturbances that can be acutely life threatening, such as diabetic ketoacidosis and a hyperglycemic hyperosmolar state. These require hospitalization for insulin administration, rehydration with intravenous fluids, and careful monitoring of electrolytes and metabolic parameters. Chronic end-organ effects of diabetes are commonly divided into microvascular and macrovascular complications. Microvascular complications occur only in individuals with diabetes and include retinopathy, nephropathy, and neuropathy, which are specific to diabetes. Macrovascular complications related to atherosclerosis, such as myocardial infarction and stroke, occur more frequently in individuals with diabetes but are not diabetes specific. In the U.S., diabetes is the leading cause of blindness in adults, the leading reason for renal failure requiring dialysis or renal transplantation, and the leading cause of nontraumatic lower extremity amputations. Evidence from clinical trials indicated that most of these diabetes-related complications can be prevented, delayed, or reduced by chronic, effective glucose lowering.

The mechanisms by which long-standing hyperglycemia causes end-organ complications are unclear. There is experimental evidence to suggest roles for AGEs (advanced glycosylation end products), increased glucose metabolism via the sorbitol pathway, increased formation of diacylglycerol leading to PKC activation, and increased flux through the hexosamine pathway. Growth factors such as VEGF-A (vascular endothelial growth factor-A) may be involved in diabetic retinopathy and TGF-β in diabetic nephropathy.

Therapy of Diabetes

Goals of Therapy

The goals of therapy for diabetes are to alleviate the symptoms related to hyperglycemia (fatigue, polyuria, weight loss) and to prevent or reduce the acute metabolic decompensation and chronic end-organ complications.

Glycemic control is assessed using both short-term (blood glucose self-monitoring; continuous glucose monitoring) and long-term (A1c, fructosamine) metrics. Using capillary blood glucose measurements, patients can measure capillary blood glucose throughout their usual fasting and feeding periods and report these values to the diabetes management team. Continuous glucose monitoring of interstitial glucose is a rapidly evolving technology that allows near real-time tracking of blood glucose levels and is being used more frequently in the management of type 1 diabetes. A1c reflects glycemic control over the prior 3 months, whereas measures of glycosylated serum proteins or albumin (fructosamine) reflect glycemic control over the preceding 2 weeks.

The term comprehensive diabetes care describes optimal therapy, which involves more than glycemic management and includes treatment of abnormalities in blood pressure and lipids and detection and management of diabetes-related complications (Figure 47–6). Table 47–4 shows the ADA-recommended treatment goals for comprehensive diabetes care for glucose, blood pressure, and lipids (see Chapters 28 and 33). The treatment goals should be individualized to the patient and take into account factors such as risk of hypoglycemia, life expectancy, age, other medical conditions, duration of diabetes, and advanced macrovascular/microvascular complications of diabetes (Cahn et al., 2015). (See Table 47–4). Also, the patient’s attitude toward diabetes, expectations, resources, and support systems should be considered. Costs of the various agents are compared in Table 47–8.

Nonpharmacologic Aspects of Diabetes Therapy

The patient with diabetes should be educated about nutrition, exercise, and medications aimed at lowering the plasma glucose (American Diabetes Association, 2017). In type 1 diabetes, matching caloric intake and insulin dosing is important. In type 2 diabetes, the diet is directed at weight loss and reduction of blood pressure and atherosclerotic risk. There is now compelling evidence that metabolic surgery can prevent or even reverse type 2 diabetes, with clinical trials showing greater efficacy than medical management (Rubino et al., 2016).

Insulin Therapy

Insulin is the mainstay for treatment of virtually all patients with type 1 and many with type 2 diabetes (Cefalu et al., 2015). Although there are specific preparations of insulin that may be administered intramuscularly,
**Insulin Formulations**

Preparations of insulin are classified according to their duration of action into short acting and long acting (Table 47–5). Within the short-acting category, it is common to distinguish the very rapid-acting insulins (aspart, glulisine, lispro) from regular insulin. Likewise, some distinguish formulations with a longer duration of action (degludec, detemir, glargine) from NPH insulin. Two approaches are used to modify the absorption and pharmacokinetic profile of insulin. The first approach is based on formulations that slow the absorption following subcutaneous injection. The other approach is to alter the amino acid sequence or protein structure of human insulin so that it retains its ability to bind to the insulin receptor, but its behavior in solution or following injection is either accelerated or prolonged in comparison to native or regular insulin (Figure 47–7). There is wide variability in the kinetics of insulin action amongst individuals and even with repeated doses in the same individual. The time to peak hypoglycemic effect and insulin levels can vary by 50%, due in part by large variations in the rate of subcutaneous absorption.

**Short-Acting Regular Insulin.** Native or regular insulin molecules associate as hexamers in aqueous solution at a neutral pH, and this aggregation slows absorption following subcutaneous injection. Regular insulin should be injected 30–45 min before a meal. Regular, unbuffered, 100-units/mL insulin also may be given intravenously or intramuscularly. However, unbuffered, regular insulin (500 units/mL) is for subcutaneous injection only and should not be given by intravenous or intramuscular injection.

**Short-Acting Insulin Analogues.** The short-acting insulin analogues are absorbed more rapidly from subcutaneous sites than regular insulin (see Figures 47–7 and 47–8; see Table 47–5) (Kerr et al., 2013). Insulin analogues should be injected 15 min or less before a meal. The time-action profile of these insulin analogues is similar. When used to treat glycemia after meals, the short-acting analogues have lower rates of hypoglycemia and modestly improved A1c levels compared to regular insulin. Insulin lispro is identical to human insulin except at positions B28 and B29. Unlike regular insulin, lispro dissociates into monomers almost instantaneously following injection. This property results in the characteristic rapid absorption and shorter duration of action compared with regular insulin.

Insulin aspart is formed by the replacement of proline at B28 with aspartic acid, reducing self-association. Like lispro, insulin aspart dissociates rapidly into monomers following injection.

Insulin glulisine is formed when glutamic acid replaces lysine at B29 and lysine replaces asparagine at B3; these substitutions result in a reduction in self-association and rapid dissociation into active monomers.

**Long-Acting Insulins.** NPH insulin (insulin isophane) is a suspension of native insulin complexed with zinc and protamine in a phosphate buffer. This produces a cloudy or whitish solution in contrast to the clear appearance of other insulin solutions. NPH insulin dissolves more gradually when injected subcutaneously; thus, its duration of action is prolonged. NPH insulin is usually given either once a day (at bedtime) or twice a day in combination with short-acting insulin.

Insulin glargine is a long-acting analogue of human insulin. Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position 21 on the A chain is replaced with glycine. Insulin glargine is a clear solution with a pH of 4.0, which stabilizes the insulin hexamer. When injected into the neutral pH of the subcutaneous space, aggregation occurs, resulting in prolonged, predictable, absorption from the injection site. Owing to insulin glargine’s acidic pH, it cannot be mixed with short-acting insulin preparations that are formulated at a neutral pH. Glargine has a sustained peakless absorption profile and provides more predictable 24-h insulin coverage than NPH insulin when injected once daily. Clinical trial data suggest that glargine has a lower risk of hypoglycemia, particularly overnight compared to NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and does not accumulate after several injections. Different preparations are

*Goals should be individualized for each patient and may be different for certain patient populations (lower or higher). According to the ADA, “Goals should be individualized based on duration of diabetes, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness, and individual patient considerations.”

§Achieving A1c value is primary goal.

§At 1–2 h after beginning of a meal.

§Lower BP targets (<130/80) may be appropriate for certain individuals with diabetes.

§For individuals with acute coronary syndrome and LDL > 50 mg/dL (1.3 mmol/L) or who cannot tolerate high-dose statins, see Chapter 33. More detailed recommendations can be found in American Diabetes Association, 2017. ASCVD, arteriosclerotic cardiovascular disease.

Figure 47–7 Insulin analogues. Modifications of native insulin can alter its pharmacokinetic profile. Reversing amino acids 28 and 29 in the B chain (lispro) or substituting Asp for Pro<sup>29B</sup> (aspart) gives analogues with reduced tendencies for molecular self-association that are faster acting. Altering Asp<sup>29B</sup> to Lys and Lys<sup>B29(Nεhexadecanoyl-γ-Glu)</sup> des(B30) human insulin. When degludec is injected subcutaneously, it forms multihexameric complexes that slow absorption; degludec also binds well to albumin; these two characteristics contribute to the prolonged effect of degludec (>24 h at steady state).

Insulin degludec is an insulin analogue modified by the addition of a saturated fatty acid to the ε amino group of LysB29, yielding a myristoylated insulin. When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. In patients with type 1 diabetes, insulin detemir, administered twice a day, has a smoother time-action profile and produces a reduced prevalence of hypoglycemia than NPH insulin. The absorption profiles of glargine and detemir insulin are similar, but detemir often requires twice-daily administration.

Insulin degludec is a modified insulin with one amino acid deleted (threonine at position B30) and is conjugated to hexadecanedioic acid via γ-L-glutamyl spacer at the amino acid lysine at position B29. Degludec, which is active at a physiologic pH, forms multihexamers after injection subcutaneously. It has less severe hypoglycemia than glargine.

Other Insulin Formulations. Stable combinations of short-acting and long-acting insulins provide convenience by reducing the number of daily injections.

Inhaled insulin (Afrezza) is formulated for inhalation using a manufacturer-specific device (Leahy, 2015). This formulation should be used in combination with a long-acting insulin and has a more rapid onset and shorter duration than injected insulin analogues. It is not widely used. Adverse events include cough and throat irritation. It should not be used in individuals who smoke.

Insulin Delivery Most insulin is injected subcutaneously. Pen devices containing prefilled insulin have proven to be popular. Jet injector systems that enable patients to receive subcutaneous insulin injections without a needle are available. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly, such as during the periorioperative period, during labor and delivery, and in intensive care situations. Long-acting insulin should not be given intravenously or intramuscularly or in an infusion device.
figure 47–8/ commonly used insulin regimens. panel a shows administration of a long-acting insulin like glargine (detemir or degludec) could also be used; detemir may require twice-daily administration; degludec is used once daily; see text for details) to provide basal insulin and a premeal short-acting insulin analogue (see table 47–5). panel b shows a less-intensive insulin regimen with twice-daily injection of nph insulin providing basal insulin and regular insulin or an insulin analogue providing mealtime insulin coverage. only one type of short-acting insulin would be used. panel c shows the insulin level attained following subcutaneous insulin (short-acting insulin analogue) by an insulin pump programmed to deliver different basal rates. at each meal, an insulin bolus is delivered. here, b indicates breakfast, l lunch, s supper, and hs bedtime. an upward arrow shows insulin administration at mealtimes. (reprinted with permission from kaufman fr, ed. medical management of type 1 diabetes, 6th ed. american diabetes association, alexandria, va. 2012. copyright © 2012 by the american diabetes association.)

continuous subcutaneous insulin infusion. short-acting insulins are the only form of the hormone used in subcutaneous insulin infusion devices. a number of pumps are available for csii therapy; this technology is rapidly evolving with improvements in hardware and software (mccadams and rizvi, 2016). insulin infusion devices provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the rise in blood glucose that occurs just prior to awakening from sleep (the dawn phenomenon) and bolus injections that are programmed according to the size and nature of a meal. selection of the most appropriate patients is extremely important for success with csii. pump infusion devices can produce a more physiological profile of insulin replacement during exercise (where insulin production is decreased) and thus less hypoglycemia than traditional subcutaneous insulin injections provide. the technology for combining an insulin infusion device and continuous glucose monitoring is rapidly evolving with algorithms that alter the infusion rate (thabit and hovorka, 2016).

factors that affect insulin absorption
factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscally rather than subcutaneously). increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption. the abdomen currently is the preferred site of injection in the morning because insulin is absorbed 20%–30% faster from that site than from the arm. rotation of insulin injection sites is recommended to avoid or limit subcutaneous scarring, lipohypertrophy, or lipodystrophy.

insulin dosing and regimens
a number of commonly used dosage regimens that include mixtures of insulin given in two or more daily injections are depicted in figure 47–8. for most patients, insulin-replacement therapy includes long-acting insulin (basal) and a short-acting insulin to provide prandial needs. in a mixed population of patients with type 1 diabetes, the average dose of insulin is usually 0.6–0.7 units/kg body weight per day, with a range of 0.4–1 units/kg/d. obese patients generally and pubertal adolescents may require more (about 1–2 units/kg/d) because of resistance of peripheral tissues to insulin. patients who require less insulin than 0.5 units/kg/d may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. the basal dose is usually 40%–50% of the total daily dose, with the remainder as prandial or premeal insulin. the insulin dose at mealtime should reflect the anticipated carbohydrate intake. a supplemental scale of short-acting insulin is added to the prandial insulin dose to allow correction of the blood glucose. insulin administered as a single daily dose of long-acting insulin, alone or in combination with short-acting insulin, is rarely sufficient to achieve euglycemia. more complex regimens that include multiple injections of long-acting or short-acting insulin are needed to reach this goal. in all patients, careful monitoring of therapeutic end points directs the insulin dose used. this approach is facilitated by self-monitoring of glucose, measurements of a1c, and individualization of the patient’s therapeutic regimen (table 47–4). in patients who have gastroparesis or loss of appetite, injection of a short-acting analogue postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

adverse events
hypoglycemia is the major risk that must be weighed against benefits of efforts to normalize glucose control. insulin treatment of both type 1 and type 2 diabetes is associated with modest weight gain. although uncommon, allergic reactions to recombinant human insulin may still occur as a result of reaction to the small amounts of aggregated or denatured insulin in preparations, to minor contaminants, or because of sensitivity to a component added to insulin in its formulation (proamine, znti, etc.). atrophy of subcutaneous fat at the site of insulin injection (lipatrophy) was a rare side effect of older insulin preparations. lipohypertrophy (enlargement of subcutaneous fat deposits) has been ascribed to the lipogenic action of high local concentrations of insulin.

insulin treatment of ketoacidosis and other special situations
intravenous administration of insulin is most appropriate in patients with ketoacidosis or severe hyperglycemia with a hyperosmolar state (umpierrez and korytkowski, 2016). insulin infusion inhibits lipolysis and gluconeogenesis completely and produces near-maximal stimulation of glucose uptake. in most patients with diabetic ketoacidosis, blood glucose concentrations will fall by about 10% per hour; the acidosis is corrected more slowly. as treatment proceeds, it often is necessary to administer glucose along with the insulin not only to prevent hypoglycemia but also to allow clearance of all ketones. patients with a nonketotic hyperglycemic hyperosmolar state may be more sensitive to insulin than are those with ketoacidosis. appropriate replacement of fluid and electrolytes, particularly k+, is an integral part of the therapy in both situations because there is always a major k+ deficit. a long-acting insulin should be administered subcutaneously before the insulin infusion is discontinued.

treatment of diabetes in children or adolescents
diabetes is one of the most common chronic diseases of childhood, and rates of type 1 diabetes in american youth are estimated at 1 in 300. an unfortunate corollary of the growing rates of obesity over the past three decades

brunton_ch47_p0863-p0886.indd   873
80/09/17  4:59 PM
is an increase in the numbers of children and adolescents with non-autoimmune, or type 2, diabetes. Current estimates are that 15%–20% of new cases of pediatric diabetes may be of type 2 diabetes; rates vary by ethnicity, with disproportionately high rates in Native Americans, African Americans, and Latinos. Current practice for type 1 diabetes is for intensive, physiologically based insulin replacement using combinations of basal and prandial insulin replacement or CSII with a goal of near-normal glucose control while avoiding hypoglycemia (Figure 47–7). The primary limiting factor of aggressive insulin therapy is hypoglycemia. In children and adolescents with type 1 diabetes, the recommended A1c goal is less than 7.5%, with a lower goal as appropriate. Insulin infusion devices and continuous glucose monitoring are being used with increasing frequency in the pediatric diabetic population and in older children and adolescents.

Because of the association of type 2 diabetes with obesity in the pediatric age group, lifestyle management is the recommended first step in therapy. Goals of reducing body weight and increasing physical activity are broadly recommended. The only medication currently approved by the FDA specifically for medical treatment of type 2 diabetes is metformin. Metformin is approved for children as young as 10 years of age and is available in a liquid formulation (100 mg/mL). Insulin is the typical second line of therapy after metformin; basal insulin can be added to oral agent therapy or multiple daily injections can be used when simpler regimens are not successful. Weight gain is a more significant problem than hypoglycemia with insulin treatment in pediatric type 2 diabetes.

Management of Diabetes in Hospitalized Patients

Hyperglycemia is common in hospitalized patients. Prevalence estimates of elevated blood glucose amongst inpatients with and without a prior diagnosis of diabetes range between 20% and 100% for patients treated in ICUs and 30% and 83% outside the ICU. Stress of illness has been associated with insulin resistance, possibly the result of counterregulatory hormone secretion, cytokines, and other inflammatory mediators. Food intake is often variable due to concurrent illness or preparation for diagnostic testing. Medications used in the hospital, such as glucocorticoids or dextrose-containing intravenous solutions, can exacerbate tendencies toward hyperglycemia. Finally, fluid balance and tissue perfusion can affect the absorbance of subcutaneous insulin and the clearance of glucose. Therapy of hyperglycemia in hospitalized patients needs to be adjusted for these variables. Emerging data indicate that hyperglycemia portends poor outcomes in hospitalized patients.

Insulin is the cornerstone of treatment of hyperglycemia in hospitalized patients. Oral agents have a limited place in treatment of hyperglycemic patients in the hospital because of slow onset of action, insufficient potency, need for intact GI function, and side effects. In noncritically ill hospitalized patients, a basal plus bolus correction insulin regimen, adjusted for oral intake, is optimal (Jacobi et al., 2012; McDonnell and Umpeier, 2012). Using only short-acting insulins administered in response to hyperglycemia (i.e., sliding-scale regimens) to treat diabetes in the inpatient hospital setting is not appropriate therapy. For critically ill patients and those with variable blood pressure, edema, and tissue perfusion, intravenous insulin is the treatment of choice. Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth. The ADA suggests blood glucose targets of 140–180 mg/dL (7.8–10.0 mM) in most hospitalized patients with more stringent goals, such as 110–140 mg/dL (6.1–7.8 mmol/L) in some critically ill patients (if achievable without significant hypoglycemia).

Insulin Secretagogues and Glucose-Lowering Agents

A variety of sulfonylureas, meglitinides, GLP-1 agonists, and inhibitors of DPP-4 are used as secretagogues to stimulate insulin release (Table 47–6).

**K \(_{ATP}\) Channel Modulators: Sulfonylureas**

First-generation sulfonylureas (tolbutamide, tolazamide, and chloropropamide) are rarely used now in the treatment of type 2 diabetes. The second, more potent, generation of hypoglycemic sulfonylureas includes glipizide (glibenclamide), glipizide, and glimepiride (Kalra et al., 2015; Thule and Umpeier, 2014). Some are available in an extended-release (glipizide) or a micronized (glyburide) formulation.

**Mechanism of Action.** Sulfonylureas stimulate insulin release by binding to a specific site on the β cell K \(_{ATP}\) channel complex (SUR) and inhibiting its activity. K \(_{ATP}\) channel inhibition causes cell membrane depolarization and the cascade of events leading to insulin secretion (see Figure 47–3). The acute administration of sulfonylureas to patients with type 2 diabetes increases insulin release from the pancreas. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The absence of acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to downregulation of cell surface receptors for sulfonylureas on the pancreatic β cell.

**ADME.** Sulfonylureas are effectively absorbed from the GI tract. Food and hyperglycemia can reduce absorption. Sulfonylureas in plasma are largely (90%–99%) bound to protein, especially albumin. The volumes of distribution of most of the sulfonylureas are about 0.2 L/kg. Although their half-lives are short (3–5 h), their hypoglycemic effects are evident for 12–24 h, and they often can be administered once daily. The liver metabolizes all sulfonylureas, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

**Therapeutic Uses.** Sulfonylureas are used to treat hyperglycemia in type 2 diabetes. Of properly selected patients, 50%–80% respond to this class of agents. All members of the class appear to be equally efficacious. A significant number of patients who respond initially later cease to respond

*Shade dose should be lower in some patients.

*Older sulfonylureas are available, but rarely used (see text). Doses > 30 mg/d usually are divided into two doses.

*Label for administration 3–4 times daily.
to the sulfonylurea and develop unacceptable hyperglycemia (so-called secondary failure). This may occur as a result of a change in drug metabolism or more likely from a progression of β cell failure. Some individuals with neonatal diabetes or MODY-3 respond to these agents. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation, and, for the older forms, significant hepatic or renal insufficiency.

**Adverse Effects; Drug Interactions.** Sulfonylureas may cause hypoglycemic reactions, including coma. Weight gain of 1–3 kg is a common side effect of improving glycemic control with sulfonylurea treatment. Less frequent side effects include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. Rarely, patients treated with these drugs develop an alcohol-induced flush similar to that caused by disulfiram or hyponatraemia. Whether this class of drugs is associated with an increase in cardiovascular mortality remains controversial.

The hypoglycemic effect of sulfonylureas may be enhanced by various mechanisms (decreased hepatic metabolism or renal excretion, displacement from protein-binding sites). Some drugs (sulfonamides, clofibrate, and salicylates) displace the sulfonylureas from binding proteins, thereby transiently increasing the concentration of free drug. Ethanol may enhance the action of sulfonylureas and cause hypoglycemia. Hypoglycemia may be more frequent in patients taking a sulfonylurea in combination with one or more of these agents: androgens, anticoagulants, azole antifungals, chloramphenicol, fenfluramine, fluconazole, gemfibrozil, H2 antagonists, magnesium salts, methyldopa, MAOIs, probenecid, sulfonpyrazone, sulfonamides, tricyclic antidepressants, and urinary acidifiers. Other drugs may decrease the glucose-lowering effect of sulfonylureas by increasing hepatic metabolism, increasing renal excretion, or inhibiting insulin secretion (β blockers, Ca2+ channel blockers, cholestyramine, diazoxide, estrogen, hydantoin, isoniazid, nicotinic acid, phenothiazines, rifampin, sympathomimetics, thiazide diuretics, and urinary alkalinizers).

**Dosage Forms Available.** Treatment is initiated at the lower end of the dose range and titrated upward based on the patient's glycemic response. Some have a longer duration of action and can be prescribed in a single daily dose (glimepiride), whereas others are formulated as extended-release or micronized formulations to extend their duration of action (see Table 47–6). Sulfonylureas such as glipizide or glibenpiride appear safer than longer-acting sulfonylureas in elderly individuals with type 2 diabetes, but even the short-duration agents should be used with caution in elderly patients.

**K1/2** **Channel Modulators: Nonsulfonylureas**

**Repaglinide.** Repaglinide is an oral insulin secretagogue of the meglitinide class (see Table 47–6). Like sulfonylureas, it stimulates insulin release by closing K1/2 channels in pancreatic β cells (Chen et al., 2015).

The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 h. The t1/2 is about 1 h. These features allow for multiple preprandial use. Repaglinide is metabolized primarily by the liver (CYP3AA4) to inactive derivatives. Because a small proportion (~10%) is metabolized by the kidney, dosing of the drug in patients with renal insufficiency also should be performed cautiously.

The major side effect of repaglinide is hypoglycemia. Repaglinide also is associated with a decline in efficacy (secondary failure) after initially improving glycemic control. Certain drugs may potentiate the action of repaglinide by displacing it from plasma protein-binding sites (β blockers, chloramphenicol, coumarin, MAOIs, NSAIDs, probenecid, salicylates, and sulfonamide) or altering its metabolism (gemfibrozil, itraconazole, trimethoprim, cyclosporine, simvastatin, clarithromycin).

**Nateglinide.** Nateglinide is an orally effective insulin secretagogue. Nateglinide stimulates insulin secretion by blocking K1/2 channels in pancreatic β cells (Chen et al., 2015). Nateglinide promotes a more rapid but less-sustained secretion of insulin than other available oral antidiabetic agents. The drug's major therapeutic effect is reducing postprandial glycemic elevations in patients with type 2 diabetes.

Nateglinide is most effective when administered at a dose of 120 mg, three times daily, 1–10 min before a meal. It is metabolized primarily by hepatic CYPs (2C9, 70%; 3A4, 30%) and should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Some drugs reduce the glucose-lowering effect of nateglinide (corticosteroids, rifamycins, sympathomimetics, thiazide diuretics, thyroid products); others (alcohol, NSAIDs, salicylates, MAOIs, and nonselective β blockers) may increase the risk of hypoglycemia with nateglinide. Nateglinide therapy may produce fewer episodes of hypoglycemia than other currently available oral insulin secretagogues, including repaglinide. As with sulfonylureas and repaglinide, secondary failure occurs.

**Biguanides**

Metformin is the only member of the biguanide class of oral hypoglycemic drugs available for use today. Previously available biguanides, phenformin and buformin, were removed from the market in the 1970s due to unacceptable rates of associated lactic acidosis.

**Mechanism of Action.** Several mechanisms have been proposed to explain the central pharmacologic action of metformin, the reduction of HGP primarily by limiting gluconeogenesis. Metformin has specific actions on mitochondrial respiration that reduce intracellular ATP and increase AMP. Experimental evidence supports activation of AMP-dependent protein kinase (AMPK) by metformin, leading to stimulation of hepatic fatty acid oxidation, glucose uptake, and nonoxidative glucose metabolism and reduction of lipogenesis and gluconeogenesis. Metformin also inhibits the mitochondrial glycerol phosphate dehydrogenase, thereby changing the redox state of the cell. More recent evidence implicates other mechanisms, including blunting the effects of glucagon, inhibiting conversion of lactate and glycerol to glucose, and shifting the liver toward negative lipid balance.

Most of the pharmacologic effects of metformin are mediated in the liver with little effect on glucose metabolism or insulin sensitivity in skeletal muscle. Metformin has little effect on blood glucose in normoglycemic states, does not stimulate the release of insulin or other islet hormones, and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, metformin lowers blood glucose by reducing HGP and increasing glucose clearance. This last effect is not well understood because of the modest action of metformin to promote glucose uptake in peripheral tissues (e.g., skeletal muscle and adipose tissue). There is little information to support a direct effect of metformin on hepatic insulin signaling, but there are at least complementary effects of the drug to improve the dose-response relationship between insulin and hepatic glucose production.

**ADME.** Fixed-dose combinations of metformin in conjunction with glipizide, glyburide, pioglitazone, repaglinide, rosiglitazone, linagliptin, saxagliptin, sitagliptin, alogliptin, canagliflozin, dapagliflozin, and empagliflozin are available. Based on the pharmacokinetics of the common immediate-release form of metformin, it is now recommended for twice-daily administration at doses of 0.5–1.0 g. The maximum dose is 2550 mg, but therapeutic benefit starts to plateau at 2000 mg. A sustained-release preparation is available for once-daily dosing starting at 500 mg daily, with titration up to 2000 mg as necessary.

Metformin is absorbed primarily from the small intestine with a bioavailability of 70%–80%. Peak concentrations after an oral dose occur at about 2 h; the drug's plasma t1/2 is 4–5 h. The drug does not bind to plasma proteins and is excreted unchanged in the urine. The transport of metformin into hepatocytes is mediated primarily by OCT 1; renal uptake is mediated by OCT 2. Export into the urine is by MATE1/2 (multidrug and toxin extrusion proteins).

**Therapeutic Uses.** Metformin is generally accepted as the first-line treatment of type 2 diabetes and is currently the most commonly used oral agent for this condition. Metformin is effective as monotherapy and in combination with other glucose lowering medications (Means et al., 2015). African Americans may have a better response to metformin than Caucasians.
CHAPTER 47

Adverse Effects; Drug Interactions. The most common side effects (10%–25% of metformin are GI: nausea, indigestion, abdominal cramps or bloating, diarrhea, or some combination of these. Metformin has direct effects on GI function, including interference with the absorption of glucose and bile salts. Use of metformin is also associated with 20%–30% lower blood levels of vitamin B₁₂, and these levels should be monitored. Most adverse GI effects of metformin abate over time with continued use and can be minimized by starting at low doses and gradually titrating to a target dose over several weeks, as well as by having patients take the drug with meals. Most studies indicated that extended-release metformin has decreased GI side effects and can be substituted for immediate-release metformin in patients who are having difficulty tolerating the drug.

Because the previously available biguanides phenformin and buformin caused lactic acidosis, metformin has been carefully scrutinized for this side effect. Lactic acidosis associated with metformin has been rarely reported in patients with the setting of concurrent conditions that can cause poor tissue perfusion (e.g., sepsis, myocardial infarction, and congestive heart failure). However, recent analyses have raised doubts regarding whether the association of metformin with lactic acidosis is causal. Renal failure is a common comorbidity in patients with lactic acidosis associated with metformin use, and plasma metformin levels are inversely related to GFR due to reduced clearance of drug from the circulation (e.g., levels rise above the usual therapeutic range when creatinine clearance drops below 40–50 mL/min). However, in recent studies of patients with severe renal failure, including some requiring dialysis, rates of lactic acidosis were not increased in those taking metformin. The ADA suggests that metformin may be used safely when the GFR is greater than 45 mL/min/1.73 m², and that the dose should be reduced by 50%–75% when GFR is 30–45 mL/min/1.73 m².

It is important to assess renal function before starting metformin and to monitor function at least annually. Metformin should be discontinued preemptively if renal function could decline precipitously, such as before radiographic procedures that use contrast dyes and during admission to the hospital for severe illness. Metformin should not be used in patients with severe pulmonary disease, decompensated heart failure, severe liver disease, or chronic alcohol abuse. Cationic drugs that are eliminated by renal tubular secretion have the potential for interaction with metformin by competing for common renal tubular transport systems. Adjustment of metformin is recommended in patients who are taking cationic medications such as cimetidine, furosemide, and nifedipine.

Thiazolidinediones

Thiazolidinediones are ligands for the PPARγ receptor, a nuclear hormone receptor that has two isoforms and is involved in the regulation of genes related to glucose and lipid metabolism. Two thiazolidinediones are currently available to treat patients with type 2 diabetes, rosiglitazone and pioglitazone; a third, troglitazone, was removed from the market in 2000 due to hepatotoxicity.

Mechanism of Action; Pharmacological Effects. Thiazolidinediones activate PPARγ receptors, which are expressed primarily in adipose tissue with lesser expression in cardiac, skeletal, and smooth muscle cells; islet β cells; macrophages; and vascular endothelial cells. The endogenous ligands for PPARγ include small lipophilic molecules such as oxidized linoleic acid, arachidonic acid, and the prostaglandin metabolite 15d-PGJ₂. Ligand binding to PPARγ causes heterodimer formation with the retinoid X receptor and interaction with PPAR response elements on specific genes (see Chapter 3). The principal response to PPARγ activation is adipocyte differentiation. PPARγ activity also promotes uptake of circulating fatty acids into fat cells and shifts of lipid stores from extra-adipose sites to adipose tissue.

One consequence of the cellular responses to PPARγ activation is increased tissue sensitivity to insulin. Pioglitazone and rosiglitazone are insulin sensitizers and increase insulin-mediated glucose uptake by 30%–50% in patients with type 2 diabetes. Although adipose tissue seems to be the primary target for PPARγ agonists, both clinical and preclinical models support a role for skeletal muscle, the major site for insulin-mediated glucose disposal, in the response to thiazolidinediones. In addition to promoting glucose uptake into muscle and adipose tissue, the thiazolidinediones reduce HGP and increase hepatic glucose uptake. It is not clear whether thiazolidinedione-induced improvement of insulin resistance is due to direct effects on key target tissues (skeletal muscle and liver), indirect effects mediated by secreted products of adipocytes (e.g., adiponectin), or some combination of these.

Thiazolidinediones also affect lipid metabolism. Treatment with rosiglitazone or pioglitazone reduces plasma levels of fatty acids by increasing clearance and reducing lipolysis. These drugs also cause a shift of triacylglycerol stores from nonadipose to adipose tissues and from visceral to subcutaneous fat deposits. Pioglitazone reduces plasma triglycerides by 10%–15%, raises HDL cholesterol levels, and increases LDL cholesterol. In contrast, rosiglitazone has minimal effects on plasma triglycerides, and the only consistent effect on circulating lipids is an increase of LDL cholesterol.

ADME. Rosiglitazone and pioglitazone are dosed once daily. The starting dose of rosiglitazone is 4 mg, and the maximum dose should not exceed 8 mg daily. The starting dose of pioglitazone is 15–30 mg, increased up to a maximum of 45 mg daily. Both agents are absorbed within 2–3 h, and bioavailability is unaffected by food. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency, but should not be used if there is active hepatic disease. Rifampin induces hepatic CYPs and causes a significant decrease in plasma concentrations of rosiglitazone and pioglitazone; gemfibrozil impedes metabolism of the thiazolidinediones and can increase plasma levels by about 2-fold; a dose reduction is suggested with this combination. The onset of action of thiazolidinediones is relatively slow; maximal effects on glucose homeostasis develop gradually over the course of 1–3 months.

Therapeutic Uses. Thiazolidinediones enhance insulin action on liver, adipose tissue, and skeletal muscle; confer improvements in glycemic control in persons with type 2 diabetes; and cause average reductions in A1c of 0.5%–1.4%. Thiazolidinediones require the presence of insulin for pharmacological activity and are not used to treat type 1 diabetes. Both pioglitazone and rosiglitazone are effective as monotherapy and as additive therapy to metformin, sulfonylureas, or insulin. In addition, pioglitazone is marketed in a fixed-dose combination with alogliptin.

Adverse Effects; Drug Interactions. The most common adverse effects of the thiazolidinediones are weight gain and edema. Thiazolidinediones cause an increase in body adiposity and an average weight gain of 2–4 kg over the first year of treatment. The use of insulin with thiazolidinedione treatment roughly doubles the incidence of edema and amount of weight gain compared with either drug alone. Macular edema has been reported in patients using both rosiglitazone and pioglitazone, but this was not a consistent finding in recent clinical trials (Ambrosius et al., 2010).

As with other side effects of thiazolidinediones, fluid retention is dose related. Use of thiazolidinediones is associated with a mild reduction of hematocrit, which may be an effect of fluid retention, although a primary effect on hematopoiesis has not been excluded. Exposure to these drugs over several years in clinical trials has been associated with an increased incidence of heart failure of up to 2-fold (Home, 2012; Horita et al., 2015). This has generally been attributed to the effect of the drugs to cause plasma volume expansion in patients with type 2 diabetes who have an increased risk for heart failure. There does not appear to be an acute effect of pioglitazone or rosiglitazone to reduce myocardial contractility or ejection fraction.
The use of thiazolidinediones in diabetic patients without a history of heart failure, or with compensated heart failure, can be initiated, but monitoring for signs and symptoms of congestive heart failure is important, especially when insulin is also used. Thiazolidinediones should not be used in patients with moderate-to-severe heart failure. In the past, evidence suggested that rosiglitazone increased the risk of cardiovascular events (myocardial infarction, stroke). For this reason, the FDA restricted its use for several years, but this regulation has now been lifted. The connection of the drug to cardiovascular disease remains controversial; most evidence supports either mild beneficial effects of pioglitazone on overall cardiovascular events or a neutral impact. In a trial of nondiabetic individuals who had insulin resistance and a recent history of ischemic stroke or TIA, pioglitazone reduced the risk of subsequent stroke or myocardial infarction and diabetes (Kernan et al., 2016).

Treatment with thiazolidinediones has been associated with a consistent increased risk of bone fracture in women, with some studies also showing effects in men (Gilbert and Pratley, 2015). Therefore, the presence of osteoporosis and other risks for fracture should be considered before starting thiazolidinediones.

Pioglitazone and rosiglitazone are associated with a lowering of transaminases, probably reflective of reductions in hepatic steatosis (Singh et al., 2015); thus, thiazolidinediones should be withheld from patients with clinically apparent liver disease, and liver function should be monitored intermittently during treatment.

**GLP-1-Based Agents**

Incretins are GI hormones that are released after meals and stimulate insulin secretion. The best-known incretins are GLP-1 and GIP. GIP has reduced efficacy to stimulate insulin release and lower blood glucose in persons with type 2 diabetes, whereas GLP-1 is effective, and the GLP-1 signaling system has been a successful drug target.

Both GLP-1 and glucagon are derived from preproglucagon, a 180–amino acid precursor with five separately processed domains (Figure 47–9). An amino-terminal signal peptide is followed by glicentin-related pancreatic peptide, glucagon, GLP-1, and GLP-2. Processing of the protein is sequential and occurs in a tissue-specific fashion. Pancreatic α cells cleave proglucagon into glucagon and a large C-terminal peptide that includes both of the GLPs. Intestinal L cells and specific hindbrain neurons process proglucagon into a large N-terminal peptide that includes glucagon or both of the GLPs. Intestinal L cells and neurons process proglucagon cleavage is mostly through proconvertase 1/3, giving glicentin, oxyntomodulin, GLP-1, and GLP-2. IP-1, intervening peptide—1; STN, solitary tract nucleus.

GLP-1 is cleaved by dipeptidyl peptidase IV (DPP-IV) into a biologically active 30–36 amino acid fragment containing the two GLPs. In L cells and neurons, proglucagon cleavage is mostly through proconvertase 1/3, giving glicentin, oxyntomodulin, GLP-1, and GLP-2. IP-1, intervening peptide—1; STN, solitary tract nucleus.

The enzyme DPP-4, yielding a plasma t1/2 of 1–2 min; thus, the natural peptide, itself, is not a useful therapeutic agent. Two broad strategies have been taken to applying GLP-1 to therapeutics: the development of injectable, DPP-4-resistant peptide agonists of the GLP-1 receptor and the creation of small-molecule inhibitors of DPP-4 (Figure 47–10; see Table 47–6).

**GLP-1 Receptor Agonists**

Five GLP-1RAs have been approved for treatment of diabetic patients in the US (Table 47–6); a fifth, lixisenatide, is available in Europe (Madsbad, 2016; Trujillo and Nuffer, 2014).

**Exenatide.** Exendin-4, is a naturally occurring 39–amino acid reptilian peptide with 53% sequence homology to GLP-1. This peptide is a potent GLP-1RA that shares many of the physiological and pharmacological effects of GLP-1. It is not metabolized by DPP-4 and has shown extended activity following injection. Synthetic exendin-4, exenatide, is approved for use as monotherapy and as adjunctive therapy for patients with type 2 diabetes not achieving glycemic targets with other drugs.

In clinical trials, exenatide, alone or in combination with metformin, sulfonylurea, or thiazolidinedione, was associated with improved glycemic control, as reflected in an about 1% decrease in A1c and weight loss that averaged 2.5–4 kg. Evidence from clinical trials indicated that exenatide can also be used in conjunction with basal insulin. An extended-release form of exenatide is administered by subcutaneous injection once a week with greater effectiveness than twice-daily treatment.

**Liraglutide.** The liraglutide peptide is a long-acting, DPP-4-resistant form of GLP-1, but with a Lys34Arg substitution and addition of an α-glutamic acid spacer coupled to a C16 fatty acyl group at Lys39. The fatty acid side chain permits binding to albumin and other plasma proteins and accounts for an extended t1/2 that permits once-daily administration; the fatty acid also seems to offer some protection from cleavage of the N-terminus by DPP-4. The pharmacodynamic profile of liraglutide mimics GLP-1 and exenatide. In clinical trials, liraglutide caused both improvement in glycemic control and weight loss. In a single comparative trial, liraglutide reduced A1c about 30% more than exenatide (Buse et al., 2009). Liraglutide is indicated for adjunctive therapy in patients not achieving glycemic control with oral agents. Liraglutide can be added to oral agents or basal insulin. In a recent report, liraglutide reduced the risk of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke in patients with type 2 diabetes and established cardiovascular disease. Similar positive effects on cardiovascular risk have also been demonstrated in a trial of semaglutide, a compound in development with similarities to liraglutide. Other GLP-1 receptor agonists (exenatide and lixisenatide) are neutral with regards to cardiovascular risk in the trials completed to date.

**Albiglutide.** Albiglutide is a fusion protein that includes two sequential GLP-1 moieties linked to human albumin; the GLP-1 sequences are modified to prevent DPP-4 cleavage. Albiglutide is also indicated for patients...
DPP-4, an ectoenzyme located on the luminal side of capillary endothelial cells metabolizes the incretins, GLP-1, and GIP, by removing the two N-terminal amino acids. The target for DPP-4 cleavage is a proline or alanine residue in the second position of the primary peptide sequence. The truncated metabolites GLP-1[9–36] and GIP[3–42] are the major forms of the incretins in plasma and are inactive as insulin secretagogues. Treatment with a DPP-4 inhibitor increases the concentrations of intact GLP-1 and GIP.

**Mechanism of Action.** All GLP-1RAs share a common mechanism, activation of the GLP-1 receptor, a member of the glucagon receptor family of GPCRs (class B GPCRs). GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous systems, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cAMP-PKA pathway and several GEFs. GLP-1 receptor activation also initiates signaling via PKC and PI3K and alters the activity of several ion channels. In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (see Figure 47–3). Activation of GLP-1 receptors in the CNS accounts for the effects of receptor agonists on food intake and gastric emptying and for side effects such as nausea.

**ADME.** Exenatide is given as a subcutaneous injection twice daily, typically before meals. It is rapidly absorbed, reaches peak concentrations in about 2 h, and has a plasma t1/2 of 2–3 h. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. Exenatide is marketed as a pen that delivers 5 or 10 μg; dosing is typically started at the lower amount and increased as needed. There is a weekly preparation based on the embedding of exenatide in a polymeric microsphere that releases drug slowly after injection. Weekly dosing is typically started at the lower amount and increased as needed. Exenatide is marketed as a pen that delivers 5 or 10 μg; the lowest dose is for treatment initiation, with elevation to the higher doses based on clinical response.

**Lixisenatide.** Lixisenatide is a slightly longer form of exenatide-4 that has comparable pharmacodynamics. Data from a recent clinical trial of diabetic subjects with a prior history of cardiovascular disease indicated no impact of lixisenatide on recurrent events. While all of the GLP-1RAs have demonstrated efficacy as monotherapy, none is considered as a first-line agent. While there are several clinical trials available that directly compared different GLP-1RAs, in general the differences in efficacy are small relative to the overall effect of the drugs, and definitive differences await more comprehensive studies.

**Dulaglutide.** Dulaglutide is a fusion protein consisting of two linked molecules that have a modified version of GLP-1 linked to the Fc portion of a human immunoglobulin; the GLP-1 sequences are modified to protect against the action of DPP-4. Pharmacodynamics are comparable to other GLP-1RAs, and the drug can be used with other antidiabetic agents.

**Lixisenatide.** Lixisenatide is a slightly longer form of exenatide-4 that has comparable pharmacodynamics. Data from a recent clinical trial of diabetic subjects with a prior history of cardiovascular disease indicated no impact of lixisenatide on recurrent events.

**Mechanism of Action.** All GLP-1RAs share a common mechanism, activation of the GLP-1 receptor, a member of the glucagon receptor family of GPCRs (class B GPCRs). GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous systems, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cAMP-PKA pathway and several GEFs. GLP-1 receptor activation also initiates signaling via PKC and PI3K and alters the activity of several ion channels. In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (see Figure 47–3). Activation of GLP-1 receptors in the CNS accounts for the effects of receptor agonists on food intake and gastric emptying and for side effects such as nausea.

**ADME.** Exenatide is given as a subcutaneous injection twice daily, typically before meals. It is rapidly absorbed, reaches peak concentrations in about 2 h, and has a plasma t1/2 of 2–3 h. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. Exenatide is marketed as a pen that delivers 5 or 10 μg; dosing is typically started at the lower amount and increased as needed. There is a weekly preparation based on the embedding of exenatide in a polymeric microsphere that releases drug slowly after injection. Weekly exenatide is given as a suspension of 2 mg that is prepared from lyophilized material and diluted immediately prior to injection. Once in the circulation, the drug is metabolized similarly to short-acting exenatide; however, based on the extended rate of delivery, 5–6 weekly doses are required to reach therapeutic steady state.

**Liraglutide.** Liraglutide is given as a subcutaneous injection once daily. Peak levels occur in 8–12 h; the elimination t1/2 is 12–14 h. There is little renal or intestinal excretion of liraglutide; clearance is primarily through the metabolic pathways of large plasma proteins. Liraglutide is supplied in a pen injector that delivers 0.6, 1.2, or 1.8 mg of drug; the lowest dose is for treatment initiation, with elevation to the higher doses based on clinical response.

**Albiglutide.** Albiglutide has a t1/2 of 5–7 days and can be dosed weekly. It is delivered through a pen device at doses of 30 or 50 mg following reconstitution. Clearance of the drug is primarily through enzymatic degradation, although renal clearance can be inferred from the increasing plasma levels in some patients with renal impairment.

**Dulaglutide** has similar pharmacokinetic properties to albiglutide; no effects of hepatic or renal impairment on these have been demonstrated.

**Lixisenatide** has an elimination t1/2 of 3–4 h that involves a significant degree of renal clearance.

**Adverse Effects: Drug Interactions.** Intravenous or subcutaneous administration of GLP-1 causes nausea and vomiting; this is thought to be mediated through neural activation of specific CNS neurons that are activated following peripheral dosing of peptide. The doses above which GLP-1 causes GI side effects are higher than those needed to regulate blood glucose. Nonetheless, up to 30%–50% of subjects report nausea at the initiation of therapy with any of the GLP-1RAs, although the GI side effects of these drugs wane over time. Activation of GLP-1 receptors in the CNS mediates the typical delay of gastric emptying, and GLP-1 agonists may alter the pharmacokinetics of drugs that require rapid GI absorption, such as oral contraceptives and antibiotics. In the absence of other diabetes drugs that cause low blood glucose, hypoglycemia associated with GLP-1 agonist treatment is rare, but the combination of GLP-1 agonist with sulfonylurea drugs causes an increased rate of hypoglycemia compared to sulfonylurea treatment alone. Because of the reliance on renal clearance, exenatide, and probably lixisenatide, should not be given to persons with moderate-to-severe renal failure (creatinine clearance < 30 mL/min). Based on surveillance data, there is a possible association of exenatide treatment with pancreatitis; therefore, these drugs should not...
be used in persons with a history or predisposition to pancreatitis. The GLP-1 receptor is expressed by thyroid C cells. Although there is not an established clinical association with medullary carcinoma of the thyroid, GLP-1 agonists should not be given to these patients.

**DPP-4 Inhibitors**

dipeptidyl peptidase IV is a serine protease that is widely distributed throughout the body, expressed as an ectoenzyme on vascular endothelial cells, on the surface of T lymphocytes, and in a circulating form. DPP-4 cleaves the two N-terminal amino acids from peptides with a proline or alanine in the second position (Deacon and Lebovitz, 2016) and seems to be especially critical for the inactivation of GLP-1 and GIP. DPP-4 inhibitors increase the AUC of GLP-1 and GIP as stimulated by ingestion of food (see Figure 47–10). Several agents provide nearly complete and long-lasting inhibition of DPP-4, thereby increasing the proportion of active GLP-1 from 10% to 20% of total circulating GLP-1 immunoreactivity to nearly 100%. Sitagliptin, saxagliptin, linagliptin, and alogliptin are available in the U.S.; vildagliptin is available in the E.U.

**Mechanism of Action; Pharmacological Effects.** Alogliptin, linagliptin, and sitagliptin are competitive inhibitors of DPP-4; vildagliptin and saxagliptin bind the enzyme covalently. All five drugs can be given in doses that lower measurable activity of DPP-4 by more than 95% for 12 h. This causes a greater than 2-fold elevation of plasma concentrations of active GIP and GLP-1 and is associated with increased insulin secretion, reduced glucagon levels, and improvements in both fasting and postprandial hyperglycemia. Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety; chronic treatment with a DPP-4 inhibitor also does not affect body weight. DPP-4 inhibitors, used as monotherapy in type 2 diabetic patients, reduce A1c levels by an average of about 0.8%. These compounds are also effective for chronic glucose control when added to the treatment of diabetic patients receiving metformin, thiazolidinediones, sulfonylureas, and insulin, with a further reduction of A1c by about 0.5%. The effects of DPP-4 inhibitors in combination regimens appear to be additive.

**ADME.** The recommended doses of the DPP4 inhibitors are alogliptin, 25 mg daily; linagliptin, 5 mg daily; saxagliptin, 5 mg daily; sitagliptin, 100 mg daily; and vildagliptin, 50 mg once or two times daily. DPP-4 inhibitors are absorbed effectively from the small intestine. Alogliptin, saxagliptin, sitagliptin, and vildagliptin circulate primarily in unbound form and are excreted largely unchanged in the urine; lower doses should be given to patients with reduced renal function. Linagliptin binds extensively to plasma proteins and is cleared primarily by the hepatobiliary system, with little renal clearance. Only saxagliptin is metabolized by hepatic microsomal enzymes, and its dose should be lowered to 2.5 mg daily when coadministered with strong CYP3A4 inhibitors (e.g., ketoconazole, azetanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ritonavir, saquinavir, and telithromycin).

**Adverse Effects.** There are no consistent adverse effects that have been noted in clinical trials with any of the DPP-4 inhibitors. Large cardiovascular safety studies have been completed for alogliptin, saxagliptin, and sitagliptin. There was no impact of these drugs on the incidence of cardiovascular events in diabetic patients, although patients treated with saxagliptin had an increase in hospitalization for heart failure. The FDA has issued a warning that this class of drugs is rarely associated with severe joint pain. DPP-4 is expressed on lymphocytes; in the immunology literature, the enzyme is referred to as CD26. Effects on immune function bear scrutiny as more patients are treated with these compounds.

**Alpha Glucosidase Inhibitors**

α-Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α-glucosidase in the intestinal brush border (Standl and Schnell, 2012). These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects. The drugs in this class are acarbose, miglitol, and voglibose (not available in the U.S.).

**ADME.** Dosing of acarbose and miglitol are similar. Both are provided as 25-, 50-, or 100-mg tablets that are taken before meals. Treatment should start with lower doses and be titrated as indicated by balancing postprandial glucose, A1c, and GI symptoms. Acarbose is minimally absorbed; the small amount of drug reaching the systemic circulation is cleared by the kidney. Miglitol absorption is saturable, with 50%–100% of any dose entering the circulation. Miglitol is cleared almost entirely by the kidney, and dose reductions are recommended for patients with creatinine clearance less than 30 mL/min.

**Adverse Effects; Drug Interactions.** The most prominent adverse effects are malabsorption, flatulence, diarrhea, and abdominal bloating. Mild-to-moderate elevations of hepatic transaminases are reported with acarbose, but symptomatic liver disease is very rare. Cutaneous hypersensitivity has been described but is also rare. Hypoglycemia has been described when α-glucosidase inhibitors are added to insulin or to insulin secretagogues. Acarbose can decrease the absorption of digoxin; miglitol can decrease the absorption of propranolol and ranitidine. The α-glucosidase inhibitors are contraindicated in patients with stage 4 renal failure.

**Therapeutic Use.** α-Glucosidase inhibitors are indicated as adjuncts to diet and exercise in type 2 diabetic patients not reaching glycemic targets. They can also be used in combination with other oral antiabetic agents or insulin. In clinical studies, α-glucosidase inhibitors reduced A1c by 0.5%–0.8%, fasting glucose by about 1 mM, and postprandial glucose by 2.0–2.5 mM. These agents do not cause weight gain or have significant effects on plasma lipids.

**Na+–Glucose Transporter 2 Inhibitors**

SGLT2 is a Na+–glucose cotransporter located almost exclusively in the proximal portion of the renal tubule. SGLT2 is a high-affinity, low-capacity transporter that moves glucose against a concentration gradient from the tubular lumen using energy generated from Na+ flux through the epithelial cells. Renal retention of glucose is nearly complete in nondiabetic persons, and SGLT2 accounts for 80%–90% of this reclamation; the remainder is recovered by SGLT1 more distally in the tubule. Early studies in diabetic animals demonstrated that hyperglycemia could be nearly ameliorated by the naturally occurring compound phlorizin, an SGLT1 inhibitor. Based on this proof of principle, drugs that are specific inhibitors of SGLT2 have been developed to treat diabetes (Mudaliar et al., 2015; White, 2015). These agents block glucose transport in the proximal tubule and lower blood glucose by promoting urinary loss.

**Mechanism of Action; Pharmacological Effects.** SGLT2 inhibitors reduce the rate of glucose reclamation in the proximal tubule and shift the renal threshold for glucose excretion from about 180 to 50 mg/dL (10 to 2.8 mM). In monotherapy, they reduce A1c by 0.7%–1.0%, cause weight loss of 2–4 kg, and decrease blood pressure by 2–4 mm Hg. There are currently three SGLT2 inhibitors available for clinical use—canagliflozin, dapagliflozin and empagliflozin—with several other members of this class still in development. These agents are indicated for use in combination with other oral agents and insulin; such use leads to an additional decrease of A1c of 0.5%–0.7%. SGLT2 inhibitors are available in combination with metformin and DPP-4 inhibitors; a combined SGLT1/SGLT2 inhibitor is under investigation.

**ADME.** Available SGLT2 inhibitors share favorable pharmacokinetic properties. They have good oral bioavailability (60%–80%) that is not affected by food and reach peak levels 1–2 h after ingestion. They are about 90% bound to circulating proteins with half-lives of about 12 h, making them suitable for once-daily dosing. The compounds are metabolized by glucuronidation and the inactive metabolites renally excreted; there is virtually no renal excretion of the parent drugs. All three drugs are available in two doses, dapagliflozin 5 and 10 mg, canagliflozin 100 and 300 mg, and empagliflozin 10 and 25 mg.

**Adverse Effects; Drug Interactions.** The side effects of SGLT2 inhibitors are predictable from their mechanism of action. There is a small (1%–2%) increase in lower urinary tract infections and a 3%–5% increase in genital mycotic infections. Urine glucose losses cause mild diuresis, which can lead to hypotension and associated symptoms in a small percentage of, usually older, patients. Importantly, because SGLT2 inhibitors...
ultimately depend on the rate of glucose filtration to be effective, potency decreases by 40%–80% across the spectrum of stage 3 kidney disease (GFR 60–30 mL/min). SGLT2 inhibitors do not cause hypoglycemia but can increase that likelihood when combined with drugs that do.

Recent analyses of clinical trials with SGLT inhibitors suggested that they may increase the risk of fractures (FDA warning), and there is preliminary evidence that these drugs affect mineral balance and circulating levels of parathyroid hormone and 1,25-hydroxy vitamin D. Studies are ongoing to see if this is a significant problem. There have been rare cases of diabetic ketoacidosis reported in patients treated with SGLT2 inhibitors. In phase 3 clinical trials, there was no evidence that SGLT2 inhibitors had adverse effects on cardiovascular disease. Data from controlled trials indicate that empagliflozin and canagliflozin reduce the risk for major cardiovascular events. (Zinnman et al., 2015; Neal et al., 2017). Canagliflozin is associated with an increased risk of lower extremity amputation.

Other Glucose-Lowering Agents

Pramlintide. Islet amyloid peptide (amylin), is a 37–amino acid peptide produced in the pancreatic β cell and secreted with insulin. A synthetic form of amylin with several amino acid modifications to improve bioavailability, pramlintide, has been developed as a drug for the treatment of diabetes (Bower and Hay, 2016). Pramlintide likely acts through the amylin receptor in specific regions of the hindbrain. Activation of the amylin receptor reduces glucagon secretion, delays gastric emptying, and fosters a feeling of satiety.

ADME. Pramlintide is administered as a subcutaneous injection prior to meals. The drug is not extensively bound by plasma proteins and has a t1/2 of 50 min. Metabolism and clearance are primarily renal. The doses in patients with type 1 diabetes start at 15 μg and are titrated upward to a maximum of 60 μg; in type 2 diabetes, the starting dose is 60 μg, and the maximum is 120 μg. Because of differences in the pH of the solutions, pramlintide should not be administered in the same syringe as insulin.

Adverse Effects; Drug Interactions. The most common adverse effects are nausea and hypoglycemia. Although pramlintide alone does not lower blood glucose, addition to insulin at mealtimes can cause increased rates of hypoglycemia, occasionally severe. It is currently recommended that prandial insulin doses be reduced 30%–50% at the time of pramlintide initiation and then titrated. Because of its effects on GI motility, pramlintide is contraindicated in patients with gastroparesis or other disorders of motility. Pramlintide is a pregnancy category C drug. Pramlintide can be used in persons with moderate renal disease (creatinine clearance > 20 mL/min).

Therapeutic Uses. Pramlintide is approved for treatment of types 1 and 2 diabetes as an adjunct in patients who take insulin with meals. Pramlintide is now being evaluated as a drug for weight loss in nondiabetic persons.

Bile Acid–Binding Resins. The only bile acid sequestrant specifically approved for the treatment of type 2 diabetes is colesevelam.

Mechanism of Action. Bile acid metabolism is abnormal in patients with type 2 diabetes, and there have been intermittent reports that bile acid–binding resins lower plasma glucose in diabetic patients. The mechanism by which bile acid binding and removal from enterohepatic circulation lowers blood glucose has not been established. Bile acid sequestrants could reduce intestinal glucose absorption, although there is no direct evidence of this. Bile acids also act as signaling molecules through nuclear receptors, some of which may act as glucose sensors.

ADME. Colesevelam is provided as a powder for oral solution and as 625-mg tablets; typical usage is 3 tablets twice daily before lunch and dinner or 6 tablets prior to the patient’s largest meal. The drug is absorbed from the intestinal tract only in trace amounts, so its distribution is limited to the GI tract.

Adverse Effects; Drug Interactions. Common side effects of colesevelam are GI, with constipation, dyspepsia, abdominal pain, and nausea affecting up to 10% of treated patients. Like other bile acid–binding resins, colesevelam can increase plasma triglycerides in persons with an inherent tendency to hypertriglyceridemia and should be used cautiously in patients with plasma triglycerides greater than 200 mg/dL. Colesevelam can interfere with the absorption of commonly used agents (e.g., phenytoin, warfarin, verapamil, glyburide, L-thyroxine, and ethinyl estradiol and fat-soluble vitamins). Colesevelam is a pregnancy category B drug that has no contraindications in patients with renal or liver disease.

Therapeutic Uses. Colesevelam is approved for treatment of hypercholesterolemia and may be used for treatment of type 2 diabetes as an adjunct to diet and exercise. In clinical trials, colesevelam reduced A1C by 0.5% when added to metformin, sulfonylurea, or insulin treatment in type 2 diabetic patients.

Bromocriptine. A formulation of bromocriptine, a dopamine receptor agonist, is approved for the treatment of type 2 diabetes. Bromocriptine is an established treatment of Parkinson disease and hyperprolactinemia (see Chapters 13, 18, and 42). Effects of bromocriptine on blood glucose are modest and may reflect an action in the CNS. The dose range for bromocriptine is 1.6 to 4.8 mg, taken with food in the morning within 3 h of awakening. Side effects include nausea, fatigue, dizziness, orthostatic hypotension, vomiting, and headache.

Combined Pharmacological Approaches to Type 2 Diabetes

Managing the Progression of Type 2 Diabetes.

For most patients, the pathologic changes causing hyperglycemia in type 2 diabetes progress over time. Thus, most patients require step-wise intensification of therapy to maintain glycemic goals. Several academic societies and health organizations have issued guidelines, approaches, algorithms, or flowcharts for the treatment of type 2 diabetes (Chamberlain et al., 2016; Garber et al., 2016). Figure 47–11 presents a simplified version; more details can be found in guidelines from the ADA, European Society for Study of Diabetes, American Association of Clinical Endocrinology, and National Institute for Health and Care Excellence (United Kingdom). Table 47–7 summarizes available pharmacological agents for the treatment of diabetes. While there is no consensus as to preferred combinations or the order in which they are used, in general selection involves consideration of side effect profile, cost and A1C goal. Recent results suggest that individuals with type 2 diabetes who are at high risk for cardiovascular disease benefit from SGLT2 inhibitors and GLP-1 agonists.

There is consensus that metformin and lifestyle changes should be the first interventions. After that, a number of pathways or combination of drugs can be used for treatment of type 2 diabetes if the glucose control does not reach the therapeutic target (Brietzke, 2015; Ismail-Beigi, 2012). For example, the addition of a second oral agent may provide good therapeutic results. Combinations of fixed doses of most of the oral agents are now available; while most oral agents have additive effects, no specific combinations have been demonstrated to have particular efficacy that can be predicted for most patients. Another approach is to introduce basal long-acting insulin (at bedtime) in combination with an oral glucose-lowering agent. This combination allows the oral agent to provide postprandial glycemic control, while the basal insulin provides the foundation for normalizing fasting or basal glucose levels. Long-acting insulin can be combined with almost all of the oral antihyperglycemic agents in Table 47–7. The exact combination of therapies can be guided by an estimation of the β cell secretory reserve in the patient (i.e., a measurement of C-peptide level) and individualized patient glycemic goals (Lathief and Inzucchi, 2016). The progressive insulin deficiency in type 2 diabetes often makes it increasingly difficult to achieve the glycemic goal solely with oral antihyperglycemic agents; thus, often insulin is required.

Costs of Diabetes Drugs.

Treatment of diabetes can be very expensive, especially because most patients use multiple agents, as well as drugs for associated conditions such as hypertension, dyslipidemia, and cardiovascular disease. Thus, cost has become a key issue in the management of diabetic patients, an issue that can affect adherence to and choice of treatment plans (Table 47–8). Newer agents are more costly, while older drug classes like sulfonylurea and biguanides are inexpensive and available in generic formulations. In recent years, the price of insulins has increased steadily despite the addition of numerous new products to the market. The balance of cost-benefit ratio and adverse
HORMONES AND HORMONE ANTAGONISTS

Treatment of diabetes

Emerging Therapies for Diabetes

A number of immunomodulatory approaches are being investigated to prevent or block the autoimmune process central to type 1 diabetes, but none has yet shown efficacy outweighing adverse events. Activators of GK, glucagon antagonists, and inhibitors of 11β-hydroxysteroid dehydrogenase are being investigated as novel therapies for type 2 diabetes (Bailey et al., 2016). Advances in protein chemistry have allowed the development of peptides that activate more than one receptor to improve glucose regulation. Most of these incorporate GLP-1 receptor agonism with the capacity to activate receptors for glucagon, GIP, or gastrin. These compounds have been potent in pre-clinical models and are now in human trials. Some drugs developed for type 2 diabetes are being tested as adjunctive therapy for type 1 diabetes (Frandsen et al., 2016).

Hypoglycemia

In the absence of prolonged fasting, healthy humans almost never have blood glucose levels below 3.5 mM. This is due to a highly adapted neuroendocrine counterregulatory system that prevents acute hypoglycemia, a hazardous and potentially lethal situation. The three major clinical scenarios for hypoglycemia are as follows:

- Treatment of diabetes
- Inappropriate production of endogenous insulin or an insulinlike substance by a pancreatic islet tumor (insulinoma) or a nonislet tumor
- Treatment (purposful or inadvertent) with a glucose-lowering agent in an individual without diabetes

Hypoglycemia in the first and third scenarios can occur in either the fasting or the fed state, whereas hypoglycemia secondary to neoplasms occurs almost exclusively in the fasting or postabsorptive state. Some drugs not used for the treatment of diabetes promote hypoglycemia (see Table 47–7).

Hypoglycemia is an adverse reaction to a number of oral therapies and is most pronounced and serious with insulin therapy. Hypoglycemia may result from an inappropriately large dose of insulin, from a mismatch between the time of peak delivery of insulin and food intake, or from superposition of additional factors that increase sensitivity to insulin (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). Hypoglycemia is the major risk that always must be weighed against benefits of efforts to normalize glucose control. Hypoglycemia is especially problematic in the elderly and should be given strong consideration when individualizing glycemic goals.

The first physiological response to hypoglycemia is a reduction of endogenous insulin secretion, which occurs at a plasma glucose level of about 70 mg/dL (3.9 mM); thereafter, the counterregulatory hormones (EPI, NE, glucagon, growth hormone, and cortisol) are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60–70 mg/dL (3.3–3.9 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., most important neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms. Severe hypoglycemia can lead to seizure and coma.

In patients with type 1 and type 2 diabetes of longer duration, the glucose secretory response to hypoglycemia becomes deficient. Diabetic patients thus become dependent on EPI for counterregulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases, especially in individuals with hypoglycemia unawareness and autonomic neuropathy. With the ready availability of home glucose

**Agents Used to Treat Hypoglycemia**

Glucagon, a single-chain polypeptide of 29 amino acids now produced by recombinant DNA technology, interacts with the glucagon GPCR on the plasma membrane of target cells, most importantly the hepatocyte, activating the G<sub>i</sub>-cAMP-PKA pathway. Glucagon should be prescribed for individuals at risk for severe hypoglycemia, and the patient’s family or friends should be trained to inject this in an emergency. Glucagon is monitored, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia. Mild-to-moderate hypoglycemia may be treated simply by ingestion of oral glucose (15–20 g of carbohydrate). When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon.

used to treat severe hypoglycemia when the diabetic patient cannot safely consume oral glucose and intravenous glucose is not available.

For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously. The intramuscular route is preferred in such an emergency. The hyperglycemic action of glucagon is transient and may be inadequate if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given oral glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects. Formulations of glucagon that can be administered as an intranasal powder have shown promising results in early phase trials.

**Other Pancreatic Islet–Related Hormones or Drugs**

**Diazoxide**

Diazoxide is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally. Diazoxide interacts with the K$_{ATP}$ channel on the β cell membrane and either prevents its closing or prolongs the open time. This effect, opposite to that of the sulfonylureas (see Figure 47–3), inhibits insulin secretion.

The usual oral dose is 3–8 mg/kg per day in adults and children and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a $t_{1/2}$ of about 48 h.

Diazoxide has a number of adverse effects, including retention of Na$^+$ and fluid, hyperuricemia, hypertrichosis, thrombocytopenia, and leukopenia, which sometimes limit its use. Despite these side effects, the drug may be useful in patients with inoperable insulinomas and in children with neonatal hyperinsulinism.

**Somatostatin**

Somatostatin is produced by δ cells of the pancreatic islet, by cells of the GI tract, and in the CNS. SST, which circulates primarily as 14– or a 28–amino acid forms, acts through a family of five GPCRs, SSTR$_{1–5}$. SST inhibits a wide variety of endocrine and exocrine secretions, including TSH (thyroid stimulating hormone) and GH (growth hormone) from the pituitary, and gastrin, motilin, VIP, glicentin, insulin, glucagon, and pancreatic polypeptide from the GI tract/pancreatic islet. The physiological role of SST has not been defined precisely, but its short $t_{1/2}$ (3–6 min) prevents its use therapeutically. Longer-acting analogues such as octreotide and lanreotide are useful for treatment of severe secretory diarrhea (Chapter 50) and carcinoid tumors, glucagonomas, VIPomas, acromegaly, and Cushing disease (Chapter 42) (Baldelli et al., 2014). Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the SST analogues, as do GI symptoms.

<tr>
<td><strong>Insulin Formulations</strong></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
| Insulin—short acting (regular) | • Type 1 and type 2 diabetes  
• Control prandial rise in blood glucose  
• Acute correction of hyperglycemia  
• Intravenous infusion for DKA and hyperglycemia in hospitalized setting | • Injected SC, IM, or IV  
• Onset of action 30–45 min after subcutaneous injection  
• Duration of action of 4–6 h after subcutaneous injection  
• Major adverse event: hypoglycemia |
| Insulin analogues—short acting (lispro, aspart, glulisine) | • Type 1 and type 2 diabetes  
• Control prandial rise in blood glucose  
• Used in insulin pump for treatment of diabetes | • Genetically modified to accelerate insulin absorption profile  
• Injected SC or IM  
• Onset of action 5–15 min after SC injection  
• Duration of action of 3–4 h after SC injection  
• Major adverse event: hypoglycemia |
| Insulin—long acting (NPH) | • Provide basal insulin in type 1 and type 2 diabetes  
• Reduce fasting hyperglycemia in type 2 diabetes | • Formulated to prolong insulin absorption  
• Usually requires twice-daily subcutaneous injection to provide 24-h basal insulin coverage  
• Combined with short-acting insulin in basal/bolus regimen  
• Given at bedtime in type 2 diabetes to reduce hepatic glucose production  
• Duration of action of 8–12 h  
• Major adverse event: hypoglycemia |
| Insulin analogues—long acting (glargine, detemir, degludec) | • Provide basal insulin in type 1 and type 2 diabetes | • Genetically modified to prolong absorption  
• Once-a-day subcutaneous injection ⇒ 24-h basal insulin coverage  
• Combined with short-acting insulin in basal/bolus regimen  
• Duration of action of 18–42 h  
• Major adverse event: hypoglycemia |
| **Oral Glucose-Lowering Agents** | | |
| Biguanides (metformin) | • Therapy of type 2 diabetes  
• Usually initial agent in type 2 diabetes | • Reduce hepatic glucose production  
• Weight neutral  
• Do not cause hypoglycemia  
• Adverse events include diarrhea, nausea, lactic acidosis (black-box warning)  
• Use cautiously in renal insufficiency, hospitalized patients; temporarily discontinue therapy prior to potential renal insults (e.g., radiocontrast media)  
• Avoid use in patients with hepatic dysfunction  
• Can be combined with other agents  
• Inexpensive |
| α-Glucosidase inhibitors | Acarbose, miglitol, voglibose | • Therapy of type 2 diabetes  
• Reduce carbohydrate breakdown in GI tract  
• Adverse effects: GI flatulence, elevated liver function tests  
• Can be combined with other agents  
• Relatively modest glucose lowering |
| Dipeptidyl peptidase 4 inhibitors | Sitagliptin, saxagliptin, linagliptin, alogliptin, vildagliptin | • Therapy of type 2 diabetes  
• Prolong action of GLP-1; promotes insulin secretion  
• Can be combined with other agents  
• Relatively modest glucose lowering |
| Insulin secretagogues—sulfonylureas  
Second generation: glyburide, glibenclamide, glipizide, and others | • Therapy of type 2 diabetes | • Stimulate insulin secretion  
• Major adverse event is hypoglycemia  
• Adjustments needed in renal/liver disease  
• Never agents more potent; may have better safety profile than first-generation agents  
• Can be combined with other agents  
• Modest weight gain  
• Inexpensive |
| Insulin secretagogues—nonsulfonylureas  
Repaglinide, nateglinide | • Therapy of type 2 diabetes | • ↑ Insulin secretion; quicker onset and shorter duration than sulfonylureas  
• Major adverse event: hypoglycemia  
• Adjustments needed in renal/liver disease  
• Can be combined with other agents |
| SGLT2 inhibitors  
Canagliflozin, dapagliflozin, empagliflozin | • Therapy of type 2 diabetes | • Prevent glucose reabsorption and promote renal glucose excretion  
• Mild weight loss and BP reduction  
• Do not cause hypoglycemia  
• May ↑ rate of lower urinary tract and genital mycotic infections, hypotension, and DKA  
• Can be combined with other agents |
### Other Glucose-Lowering Agents (continued)

| Thiazolidinediones | • Therapy of type 2 diabetes | • Increase insulin sensitivity  
|                    |                           | • Adverse effects: peripheral edema, CHF, weight gain, fractures, macular edema  
| Rosiglitazone, pioglitazone |                           | • Use with caution in CHF, liver disease  
|                     |                           | • Can be combined with other agents  

### Other Glucose-Lowering Agents

| GLP-1 agonists | • Therapy of type 2 diabetes | • ↑ Insulin secretion, ↓ gastric emptying, ↓ glucagon  
|----------------|----------------------------|-----------------------------------------------------------------  
| Albiglutide, dulaglutide, exenatide, lixisenatide |                           | • Injected subcutaneously  
|                     |                           | • Often associated with weight loss  
|                     |                           | • Adverse events include nausea  
|                     |                           | • Do not use with agents that ↓ GI motility  
|                     |                           | • Risk of hypoglycemia with insulin  

| Amylin analogue | • Adjunctive therapy with insulin in type 1 and type 2 diabetes | • Slow gastric emptying, decreases glucagon  
|----------------|---------------------------------------------------------------|-----------------------------------------------------------------  
| Pramlintide |                           | • Injected subcutaneously  
|                     |                           | • ↓ Postprandial glycaemia  
|                     |                           | • Often associated with weight loss  
|                     |                           | • Adverse events include nausea  
|                     |                           | • Do not use with agents that ↓ GI motility  
|                     |                           | • Risk of hypoglycemia with insulin  

### Drugs to Reverse Hypoglycemia

| Glucagon | • Emergency treatment of severe hypoglycaemia | • Injected SC, IM, or IV  
|          | • Diagnose for GI radiographic examination | • Quickly raises blood glucose  
|          |                                          | • Releases smooth muscles of the GI tract  
|          |                                          | • ↑ Inotropic and chronotropic on heart  

### Other Pancreatic Islet-Related Hormones or Drugs

| Diazoxide | • Treatment of hypertensive crisis | • Inhibits insulin secretion  
|           | • Treatment of pathologic hyperinsulinemia | • Adverse events include nausea, vomiting, fluid retention, hyperuricemia, hypertriglyceridemia, thrombocytopenia, and leukopenia

### Bibliography

This chapter presents a primer on mineral ion homeostasis and the endocrinology of Ca\(^{2+}\) and phosphate metabolism, then some relevant pathophysiology, and finally pharmacotherapeutic options in treating disorders of mineral ion homeostasis.

### Physiology of Mineral Ion Homeostasis

**Calcium**

Elemental calcium is essential for many biological functions, ranging from muscle contraction and intracellular signaling (see Chapter 3) to blood coagulation and supporting the formation and continuous remodeling of the skeleton.

Extracellular Ca\(^{2+}\) is in the millimolar range, whereas intracellular free Ca\(^{2+}\) is maintained at submicromolar levels. Different mechanisms evolved that regulate Ca\(^{2+}\) over this 10,000-fold concentration span. Changes in cytosolic Ca\(^{2+}\) (whether released from intracellular stores or entering via membrane Ca\(^{2+}\) channels) can modulate effector targets, often by interacting with the ubiquitous Ca\(^{2+}\)-binding protein calmodulin. The rapid association-dissociation kinetics of Ca\(^{2+}\) permit effective regulation of cytosolic Ca\(^{2+}\) over the range of 100 nM to 1 μM.

The body content of calcium in healthy adult men and women, respectively, is about 1300 and 1000 g, of which more than 99% is in bone and teeth. Ca\(^{2+}\) in extracellular fluids is stringently regulated within narrow limits. In adult humans, the normal serum Ca\(^{2+}\) concentration ranges from 8.5 to 10.4 mg/dL (2.1–2.6 mEq/L) and includes three distinct chemical forms: ionized (50%), protein bound (40%), and complexed (10%). Thus, whereas total plasma Ca\(^{2+}\) concentration is about 2.5 mM, the concentration of ionized Ca\(^{2+}\) in plasma is about 1.2 mM. The various pools of Ca\(^{2+}\) are illustrated schematically in Figure 48–1.

Albumin accounts for some 90% of the serum Ca\(^{2+}\) in normal value of 4.0 g/dL can be expected to alter total Ca\(^{2+}\) concentration by about 0.8 mg/dL. The remaining 10% of the serum Ca\(^{2+}\) is complexed with small polyvalent anions, primarily phosphate and citrate. Only dif fusible Ca\(^{2+}\) (i.e., ionized plus complexed) crosses cell membranes. The degree of complex formation depends on the ambient pH and the concentrations of ionized Ca\(^{2+}\) and complexing anions. Ionized Ca\(^{2+}\) is the physiologically relevant component, mediating calcium’s biological effects, and, when perturbed, produces the characteristic signs and symptoms of hypop- or hypercalcemia. Hormones that affect intestinal calcium absorption and renal calcium excretion tightly control the extracellular Ca\(^{2+}\) concentration; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

**Calcium Stores**

The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite; other ions, including Na\(^+\), K\(^+\), Mg\(^{2+}\), and F\(^-\), are also present in the crystal lattice. The steady-state content of Ca\(^{2+}\) in bone reflects the net effect of bone resorption and bone formation. Although the bulk of skeletal calcium is not readily available for meeting short-term needs, a rapidly exchangeable calcium pool at the endosteal surface can be both mobilized and serve to sequester acute increases of extracellular calcium.

**Calcium Absorption and Excretion**

In the U.S., about 75% of dietary Ca\(^{2+}\) is obtained from milk and dairy products. Guidelines for daily vitamin D and calcium supplementation (Institute of Medicine, 2011) are shown in Table 48–1. Figure 48–2 illustrates the components of whole-body daily Ca\(^{2+}\) turnover. Ca\(^{2+}\) enters the body only through the intestine. Vitamin D-dependent Ca\(^{2+}\) transport occurs in the proximal duodenum, whereas most Ca\(^{2+}\) uptake is mediated by passive absorption throughout the small intestine. When calcium intake is adequate or high, passive calcium absorption in the jejunal and ileum
Abbreviations

**BMD**: bone mineral density  
**CaSR**: calcium-sensing receptor  
**CGRP**: calcitonin gene–related peptide  
**CKD-MBD**: chronic kidney disease–mineral bone disease  
**CTR**: calcitonin receptor  
**CYP**: cytochrome P450  
**DHT**: dihydrotestosterone  
**ERK**: extracellular signal–regulated kinase  
**FGF**: fibroblast growth factor  
**FGF23**: fibroblast growth factor 23  
**FGFR**: FGF receptor  
**FGFR/KLOTHO**: FGF receptor/Klotho  
**FRS2a**: FGF substrate 2a  
**HRT**: hormone replacement therapy  
**HVDDR**: hereditary 1,25-dihydroxyvitamin D resistance  
**Ig**: immunoglobulin  
**IL-1**: interleukin 1  
**IP**: inositol trisphosphate  
**KLOTHO**: klotho  
**MTC**: medullary thyroid carcinoma  
**NF-kB**: nuclear factor kappa B  
**25-OH-D3**: 25-OH–cholecalciferol  
**OPG**: osteoprotegerin  
**NPT2**: Sodium–dependent phosphate transport protein 2  
**PDDR**: pseudovitamin D–deficiency rickets  
**PKC**: protein kinase C  
**PLC**: phospholipase C  
**PTH**: parathyroid hormone  
**PTHR**: PTH receptor  
**PTHRP**: PTH–related protein  
**RANK**: receptor for activating NF-κB  
**RANKL**: RANK ligand  
**REMS**: Risk Evaluation and Mitigation Strategy  
**SERM**: selective estrogen receptor modulator  
**SGK1**: serum and glucocorticoid–regulated kinase 1  
**TK**: tyrosine kinase  
**TRPV6**: Transient receptor potential cation channel V6  
**VDDR-1**: vitamin D–dependent rickets type 1  
**VDR**: vitamin D receptor  
**XLH**: X-linked hypophosphatemia

*Intake covering needs of ≥ 97.5% of population.  
†Covers all forms of vitamin D. For details, see Institute of Medicine, 2011.  
‡For infants 0 to 6 months of age, adequate intake is 200 mg/d; it is 260 mg/d for infants 6 to 12 months of age. RDAs have not been established for infants.  
§For infants 0 to 6 months of age, adequate intake is 400 IU/d; it is 400 IU/d for infants 6 to 12 months of age. RDAs have not been established for infants.
HORMONES AND HORMONE ANTAGONISTS

Hormonal regulators of intestinal phosphate absorption include glucocorticoids, estradiol, and epidermal growth factor. Nonhormonal factors contributing to phosphate homeostasis include extracellular volume and acid-base status.

Dietary phosphate deficiency upregulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of effects on plasma P, Ca\(^{2+}\), PTH, or FGF23 (Bourgeois et al., 2013). PTH and FGF23 increase urinary phosphate excretion by blocking phosphate reabsorption. Expansion of plasma volume increases urinary phosphate excretion.

**Role of Phosphate in Urine Acidification**

Phosphate is concentrated progressively as it traverses the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H\(^+\) and Na\(^+\) in the tubular urine converts Na-HPO\(_4\) to NaH\(_2\)PO\(_4\), permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H\(^+\) transport.

**Pharmacological Actions of Phosphate**

Phosphate salts are employed as mild laxatives (see Chapter 50) and to acidify the urine and treat hypophosphatemia.

---

**Figure 48–2** Whole-body daily turnover of calcium. In healthy adults, calcium intake is equal to calcium excretion, and no net gain or loss of skeletal calcium occurs. Daily dietary calcium intake averages 800 mg. Net intestinal absorption amounts to 150 mg and is balanced by an equivalent amount of calcium excretion by the kidneys. Fecal calcium excretion amounts to 650 mg. In the absence of a challenge to calcium homeostasis such as lactation, the kidneys are the primary site of calcium metabolism. (Adapted with permission from Yanagawa N, Lee DBN. Renal handling of calcium and phosphorus. In: Coe FL, Favus MJ, eds. Disorders of Bone and Mineral Metabolism. Raven Press, New York, 1992, 3–40.)

**Absorption, Distribution, and Excretion**

Phosphate is an abundant dietary component; even an inadequate diet rarely causes phosphate depletion. Phosphate is extensively absorbed from the GI tract primarily by passive movement (proportional to the concentration in the intestinal lumen), with a smaller fraction mediated by active vitamin D–dependent transport. The fact that most intestinal phosphate absorption is passive may explain why it continues in the absence of a challenge to calcium homeostasis such as lactation, the kidneys are the primary site of calcium metabolism. (Adapted with permission from Yanagawa N, Lee DBN. Renal handling of calcium and phosphorus. In: Coe FL, Favus MJ, eds. Disorders of Bone and Mineral Metabolism. Raven Press, New York, 1992, 3–40.)

**Parathyroid Hormone**

Parathyroid hormone is a polypeptide that helps to regulate plasma Ca\(^{2+}\) by affecting bone resorption/formation, renal Ca\(^{2+}\) excretion/reabsorption, and calcitriol synthesis (thus, GI Ca\(^{2+}\) absorption).

---

**Figure 48–3** Calcium homeostasis and its regulation by PTH, FGF23, and 1,25-dihydroxyvitamin D. PTH, released from parathyroids (dotted line), has stimulatory effects on bone and kidney, increasing calcium mobilization and reabsorption, decreasing phosphate reabsorption, and stimulating 1α-hydroxylase activity in kidney mitochondria, leading to the production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol (Figure 48–6). FGF23, released from bone (dotted line), likewise dampens renal phosphate reabsorption and augments calcium recovery but decreases the production of 1,25-dihydroxyvitamin D by inhibiting 25(OH)\(_2\)-α-hydroxylase (CYP27B1) and increasing metabolism by inducing 1,25(OH)\(_2\)-vitamin D 24-hydroxylase (CYP24A1). FGF23 also suppresses PTH release by the parathyroid glands. Calcitriol, the biologically active metabolite of vitamin D, increases intestinal calcium and phosphate absorption, and regulates FGF23 synthesis and release and calcium mobilization in bone.
Parathyroid hormone exerts both catabolic and anabolic effects on bone. Chronically elevated PTH enhances bone resorption and thereby increases Ca\(^{2+}\) delivery to the extracellular fluid, whereas intermittent exposure to PTH promotes anabolic actions. The primary skeletal target cell for PTH is the osteoblast.

### Effects on Kidney

In the kidney, PTH enhances the efficiency of Ca\(^{2+}\) reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, 1,25-dihydroxy vitamin D\(_3\) (calcitriol; see Figure 48–3). As a result, filtered Ca\(^{2+}\) is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized 1,25-dihydroxy vitamin D\(_3\) interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca\(^{2+}\) absorption, thereby contributing to the increase in plasma Ca\(^{2+}\).

### Calcitriol Synthesis

The final step in the activation of vitamin D to calcitriol occurs in proximal tubule cells. Three primary regulators govern the enzymatic activity of the 25-hydroxyvitamin D\(_3\)–1α-hydroxylase that catalyzes this step: PTH, Ca\(^{2+}\), and Ca\(^{2+}\) (see discussion later in this chapter). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating P and a more direct effect of the hormone on the 1α-hydroxylase lead to increased circulating concentrations of calcitriol.

### Integrated Regulation of Extracellular Ca\(^{2+}\) and Phosphate by PTH

Even modest reductions of serum Ca\(^{2+}\) stimulate PTH secretion. For minute-to-minute regulation of Ca\(^{2+}\), adjustments in renal Ca\(^{2+}\) handling suffice to maintain plasma calcium homeostasis. With prolonged hypocalcemia, the renal 1α-hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal Ca\(^{2+}\) absorption (see Figure 48–3), and delivery of Ca\(^{2+}\) from bone into the extracellular fluid is augmented. With prolonged and severe hypocalcemia, new bone-remodeling units are activated to restore circulating Ca\(^{2+}\) concentrations, albeit at the expense of skeletal integrity.

When plasma Ca\(^{2+}\) activity rises, PTH secretion is suppressed, and tubular Ca\(^{2+}\) reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate depress calcitriol production and thereby decrease intestinal Ca\(^{2+}\) absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent response to positive or negative excursions of plasma Ca\(^{2+}\) concentrations.

### Fibroblast Growth Factor 23

Fibroblast growth factor 23 is a member of the FGF19 family of endocrine FGFs. Osteocytes and other bone cells, including osteoblasts, and lining cells are the primary source of FGF23. FGF23 is secreted in response to dietary phosphorus load and to changes in serum phosphate and 1,25-dihydroxyvitamin D. Its main function is the promotion of urinary membrane-associated CasR on parathyroid cells. The CasR is a GPCR that couples with G\(_i\) and G\(_s\). Occupancy of the CasR by Ca\(^{2+}\) stimulates the G\(_i\)-PLC-IP-Ca\(^{2+}\), pathway leading to activation of PKC; this results in inhibition of PTH secretion, an unusual case in which elevation of cellular Ca\(^{2+}\) inhibits secretion (another being the granular cells in the juxtaglomerular complex of the kidney, where elevation of cellular Ca\(^{2+}\) inhibits renin secretion). Simultaneous activation of the CasR-G\(_i\) pathway by Ca\(^{2+}\) reduces cyclic AMP synthesis and lowers the activity of PKA, also a negative signal for PTH secretion. Conversely, reduced occupancy of CasR by Ca\(^{2+}\) reduces signaling through G\(_i\) and G\(_s\), thereby promoting PTH secretion. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and dopamine, also increase PTH secretion, but much less than does hypocalcemia. The active vitamin D metabolite 1,25-dihydroxyvitamin D (calcitriol) directly suppresses PTH gene expression. Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

### Chemistry

Parathyroid hormone is a single polypeptide chain of 84 amino acids with a molecular mass of about 9500 Da. Biological activity is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTHR and hormone activity. Derivatives lacking the first and second residue bind to PTHRs but do not activate the cyclic AMP or IP–Ca\(^{2+}\) signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

### Synthesis and Secretion

Parathyroid hormone is synthesized as a 115–amino acid peptide called preproparathyroid hormone, which is converted to proparathyroid hormone by cleavage of 25 amino-terminal residues in the endoplasmic reticulum. Proparathyroid hormone is converted in the Golgi complex to PTH by cleavage of six amino acids. PTH(1–84) resides within secretory granules until it is discharged into the circulation. PTH(1–84) has a t\(_1/2\) in plasma of about 4 min; removal by the liver and kidney accounts for about 90% of its clearance. Proteolysis of PTH generates smaller fragments [e.g., a 33– to 36–amino acid N-terminal fragment that is fully active, a larger C-terminal peptide, and PTH(7–84)]. PTH(7–84) and other amino-truncated PTH fragments are normally cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms.

### Physiological Functions and Mechanism of Action

The primary function of PTH is to maintain a constant concentration of Ca\(^{2+}\) and P in the extracellular fluid. The principal processes regulated are renal Ca\(^{2+}\) and P absorption and mobilization of bone Ca\(^{2+}\) (see Figure 48–3). The actions of PTH on its target tissues are mediated by at least two GPCRs that can couple with G\(_i\), G\(_s\), and G\(_\alpha\) in cell type–specific manners (Garrido et al., 2009). The type I PTHR, which also binds PTHrP, mediates mineral-ion homeostasis and the skeletal actions of PTH. A second PTHR expressed in arterial and cardiac endothelium, brain, pancreas, placenta, and elsewhere binds PTH but not PTHrP. A third putative PTHR, designated the CPTH receptor, interacts with carboxy-terminal PTH fragments that are truncated in the amino-terminal region, contain most of the carboxy terminus, and are inactive at the PTH receptor; CPTH receptors are expressed on osteocytes (Scillitani et al., 2011).

### Regulation of Secretion

Plasma Ca\(^{2+}\) is the major factor regulating PTH secretion. As the concentration of Ca\(^{2+}\) diminishes, PTH secretion increases; hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca\(^{2+}\) is high, PTH secretion decreases. Changes in plasma Ca\(^{2+}\) regulate PTH secretion by the plasma
phosphate excretion and the suppression of active vitamin D production by the kidney. FGF23, unlike PTH, also suppresses intestinal phosphate absorption.

**Synthesis and Secretion**

Fibroblast growth factor 23 is synthesized as a 251–amino acid peptide. Cleavage of the amino-terminal signal sequence and glycosylation produce the active protein consisting of an amino-terminal core sequence and a shorter carboxy-terminal fragment (Figure 48–4). FGF23 is extensively O-glycosylated, which shields it from proteolysis and enhances secretion. FGF23 possesses a furin cleavage site, RXRRX, which is cleaved by endoprotease furin. Cleavage releases a smaller 250-amino acid protein called cFGF23 (intact FGF23) and a smaller fragment of 76 amino acids called iFGF23 (inactive FGF23). cFGF23 is now thought to inhibit the FGFRs by competitively blocking binding to the extracellular domain of α-klotho. FGF23 inhibits renal phosphate transport by activating FGFRs through a mechanism that entails the transmembrane form of α-klotho. Klotho serves as an essential coreceptor for FGF23 activation and transduction of FGF23 signaling. Cleaved klotho increases FGF23 formation, while FGF23 decreases expression of transmembrane klotho (Smith et al., 2012). FGFRs are receptor TKs consisting of an extracellular domain with immunoglobulin-like loops and an intracellular region that harbors TK domains (Figure 48–4). The amino-terminal portion of FGF23 binds the FGFR, while the carboxy-terminal segment binds to klotho. This ternary complex (FGFR, klotho, and FGF23) then forms, thereby enabling intracellular TK autophosphorylation of FGFR. Intracellular signaling is achieved primarily through ERKs and PLC.

**Regulation of Secretion.** Fibroblast growth factor 23 is released from bone into the circulation in response to elevations of serum phosphate, PTH, and 1,25 vitamin D. The sensing mechanism responding to these changes and its control over FGF23 secretion is unknown. Iron deficiency also influences FGF23 levels. FGF23 is normally released by both as iFGF23 and inactive cFGF23 fragments. In healthy individuals, low serum iron is associated with elevated cFGF23 levels, but not with iFGF23. The ratio of iFGF23:cFGF23 varies appreciably in disease states and in inherited disorders of FGF23 metabolism (Wolf and White, 2014).

**Physiological Functions and Mechanism of Action**

**Effects on Kidney.** Fibroblast growth factor 23 increases phosphate excretion and lowers vitamin D formation. The phosphaturic action of FGF23 is mediated by FGFFR1c and to a lesser degree by FGFFR4 (Gattiini et al., 2014). FGF23 and PTH reduce phosphate by mechanisms that involve endocytosis and downregulation of NPT2a and NPT2c, the principal Na-phosphate cotransporters that mediate phosphate retrieval from the tubular fluid. Notably, although FGF23 and PTH exert parallel inhibitory actions on phosphate excretion, they have opposite effects on vitamin D metabolism. PTH stimulates the formation of the active form of vitamin D, whereas FGF23 reduces vitamin D levels by augmenting its metabolism to inactive forms.

Exogenous FGF23 administration reduces serum P and calcitriol synthesis. Although no clinical agents based on FGF23 have yet been developed, bioactive fragments or FGF23 inhibitors might become useful in counterbalancing the hyperphosphatemic actions of vitamin D therapy. The novel recombinant human IgG monoclonal antibody KRN23, which binds FGF23 and inhibits its activity, can increase P reabsorption and serum concentrations of P and calcitriol in patients with X-linked hypophosphatemia (Carpenter et al., 2014; Imel et al., 2015).

Soluble klotho, a circulating cleavage product of membrane-associated klotho, when administered to mice increased serum levels of FGF23 and reduced bone mineral content with a concomitant increase in fracture incidence (Smith et al., 2012). These findings suggest that a scavenging antibody directed to the soluble klotho fragment might provide an additional means to reduce FGF23 levels in patients with secondary hyperparathyroidism or CKD-MBD.

---

**Figure 48–4**  FGF23-FGFR-Klotho complex. FGF23 binding to the FGFR + klotho complex promotes dimerization of the ternary complex. FGFRs possess three Ig-like domains (I, II, III). Alternative splicing in domain III gives rise to FGFR1/2/3 isoforms. FGFR1c is believed to be the FGF23 receptor. FGF23 requires α-klotho to bind and activate FGFR1. FGF23 consists of a larger N-terminal region and shorter C-terminal segment. Intracellular proteolysis and inactivation of FGF23 occurs at a site separating the two domains. Klotho is a transmembrane protein with two large extracellular KL1 and KL2 domains that can be cleaved by a disintegrin and metalloproteinase 10 and 17 (ADAM10/17). Full-length klotho and the shed extracellular domain of KL have distinct functions. Notably, full-length klotho is coreceptor for FGFR1. Intracellular TK domains on FGFRs mediate downstream signaling, primarily through parallel pathways involving FRS2a, SGK1, ERK1/2 for FGF23 (Andrukhova et al., 2012), and PLCγ (which activates signaling by Ca2+-activating PKC) (Ornitz and Itoh, 2015).
Vitamin D (cholecalciferol) is formed in the skin by solar ultraviolet irradiation of 7-dehydrocholesterol or provided in the diet or by supplements. Sequential hydroxylation at position 25 (red) in the liver to 25(OH)D (calcidiol) and at position 1 (red) in the kidneys produces biologically active 1α,25(OH)2D3 (calcitriol). Metabolism of calcidiol and calcitriol by 24-hydroxylase reduces serum levels of 1α,25(OH)2D3 (calcitriol) and 25(OH)D3 (calcidiol) to 24,25(OH)2D3 (1α,25(OH)2D3) and 1α,24,25(OH)3D3, respectively. FGF23 reduces 1α,25(OH)2D3 levels by stimulating 24-hydroxylation by CYP24A1 and inhibiting 1α-hydroxylase (CYP27B1). Elevated calcitriol levels decrease PTH synthesis by parathyroid glands and stimulate FGF23 release from osteocytes.

**Chemistry and Occurrence**

Vitamin D is a hormone rather than a vitamin, and it plays an active role in Ca2+ homeostasis. The biological actions of vitamin D are mediated by the VDR, a nuclear receptor. Vitamin D is the name applied to two related fat-soluble substances, vitamin D3 (cholecalciferol) and vitamin D2 (ergocalciferol). Recent studies showed clearly that vitamin D3 has a potency about 10-fold greater than that of vitamin D2. This difference is likely attributable to the longer t1/2 of vitamin D3 and lower affinity of vitamin D2 metabolites for the vitamin D-binding protein (Jones et al., 2014), dispelling the long-held notion that there is no practical difference between vitamin D2 and vitamin D3. The total concentration of serum 25-hydroxyvitamin D (25-OH-D3) is now accepted as the clinical parameter for assessing vitamin D status and functional adequacy of vitamin D treatments.

The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D3). Ergosterol, present only in plants and fungi, is the provitamin for ergocalciferol (vitamin D2).

**Human Requirements and Units**

Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation, especially in winter, may necessitate dietary vitamin D supplementation (Faurschou et al., 2012). Serum levels of vitamin D vary widely, likely reflecting genetic background, diet, latitude, time spent out of doors, body size, developmental stage, and state of health, as well as plasma levels of vitamin D-binding protein, a specific a globulin. The actions of vitamin D may differ with the expression of components of the synthetic and action pathways of vitamin D. Other factors contributing to the rise of vitamin D deficiency may include diminished consumption of vitamin D–fortified foods owing to concerns about fat intake; reduced intake of dairy products; an increased prevalence and duration of exclusive breastfeeding (human milk is a poor source of vitamin D); and increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging from exposure to ultraviolet radiation. The recommended amount of sunscreen and SPF advised by the World Health Organization may abolish endogenous vitamin D production (Faurschou et al., 2012). The U.S. Institute of Medicine suggests achieving a serum level for 25-OH vitamin D of 50 nmol/L (20 ng/mL). The most recent recommended daily intakes of vitamin D and calcium are shown in Table 48–1.

**Metabolic Activation**

Vitamin D requires modification to become biologically active. The primary active metabolite, 1α,25-dihydroxy vitamin D (calcitriol), is the product of successive hydroxylations (see Figure 48–5).

**25-Hydroxylation of Vitamin D.** The initial hydroxylation occurs in the liver to generate 25-OH-cholecalciferol (25-OH3 or calcifediol) and 25-OH2D3 (ergocalciferol), respectively. 25-OH3 is the major circulating form of vitamin D3; it has a biological t1/2 of 19 days, and normal steady-state concentrations are 15–50 ng/mL, whereas 25-OH2D3 has a t1/2 of 13 days.

Figure 48–5  **Vitamin D metabolism.** Vitamin D (cholecalciferol) is formed in the skin by solar ultraviolet irradiation of 7-dehydrocholesterol or provided in the diet or by supplements. Sequential hydroxylation at position 25 (red) in the liver to 25(OH)D3 (calcidiol) and at position 1 (red) in the kidneys produces biologically active 1α,25(OH)2D3 (calcitriol). Metabolism of calcidiol and calcitriol by 24-hydroxylase reduces serum levels of 1α,25(OH)2D3, FGF23 promotes the formation of 1α,25(OH)2D3, while FGF23 reduces 1α,25(OH)2D3 levels by stimulating 24-hydroxylation by CYP24A1 and inhibiting 1α-hydroxylase (CYP27B1). Elevated calcitriol levels decrease PTH synthesis by parathyroid glands and stimulate FGF23 release from osteocytes.
1α-Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D–binding globulin. Final activation occurs primarily in the kidney, where the enzyme 25-hydroxyvitamin D-1α-hydroxylase (CYP27B1) in the proximal tubules converts 25-OHD to calcitriol. This process is highly regulated (Figures 48-3 and 48-5). Dietary deficiency of vitamin D, calcium, or phosphate stimulates 1α-hydroxylation of 25-OHD, increasing the formation of biologically active 1,25(OH)2D3. In contrast, when Ca2+ concentrations are elevated, 25-OHD is inactivated by 24-hydroxylation. Similar reactions occur with 25-OHD3 (ergocalciferol). Calcitriol controls 1α-hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma t1/2 of calcitriol is estimated at 3–5 days in humans.

24-Hydroxylation of Calcitriol. The 25(OH) vitamin D-24-hydroxylase enzyme CYP24A1 catalyzes several steps of 1,25(OH)2D3 degradation. CYP24A1 is upregulated by FGF23 and calcitriol and downregulated by PTH.

Physiological Functions and Mechanism of Action
Calcitriol augments absorption and retention of Ca2+ and phosphate and thereby helps to maintain normal concentrations of Ca2+ and phosphate in plasma. Calcitriol facilitates absorption of Ca2+ and phosphate in the small intestine, interacts with PTH to enhance their mobilization from bone, and decreases their renal excretion. The actions of calcitriol are mediated by the nuclear receptor VDR, a member of the steroid and thyroid hormone nuclear receptor superfamily. Calcitriol binds to cytosolic VDRs within target cells; the VDR-hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. Calcitriol also exerts rapid, nongenomic effects. These actions also involve the VDR but at an alternative site where calcitriol acts in a planar configuration.

Calcium is absorbed predominantly from the duodenum. In the absence of calcitriol, GI calcium absorption is inefficient and involves passive diffusion via a paracellular pathway. Ca2+ absorption is potentially augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca2+ absorption (Kellett, 2011):

- entry across mucosal membranes mediated by TRPV6 and Ca(2+)-ATPase; the precise function of calbindin-D28K is unsettled.
- active extrusion across serosal plasma membranes.

Calcitriol upregulates the synthesis of FGF23, calbindin-D28K, calbindin-D9K, and the serosal plasma membrane Ca2+-ATPase. Calbindin-D9K enhances the extrusion of Ca2+ by the Ca2+-ATPase; the precise function of calbindin-D28K is unsettled.

The primary role of calcitriol is to stimulate intestinal absorption of Ca2+, which in turn indirectly promotes bone mineralization. Hence, PTH and calcitriol act independently to enhance bone resorption. Osteoclasts, the cells responsible for bone formation, express VDR, and calcitriol induces production of several osteoblast proteins, including osteocalcin, a vitamin K–dependent protein that contains γ-carboxyglutamic acid residues, and II-1, a lymphokine that promotes bone resorption. Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. In a healthy scenario, osteoblast and osteoclast activities are coupled. Osteoporosis is a disease in which coupling is disturbed; osteoblast responsiveness to calcitriol is profoundly impaired, osteoclast activity predominates, and bone resorption exceeds formation.

Other Effects of Calcitriol. Effects of calcitriol extend well beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body. Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function. Calcitriol inhibits epidermal proliferation, promotes epidermal differentiation, and is used as a treatment of plaque psoriasis (see Chapter 70).

Calcitonin
Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH. The thyroid parafollicular C cells produce and secrete calcitonin. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation. Calcitonin acts through the CTR, a GPCR that links to Gα and Gβγ.

Regulation of Secretion
Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking cyst 1 and cyst 7. Serum [Ca2+] concentrations regulate the biosynthesis and secretion of calcitonin. Calcitonin secretion increases when serum Ca2+ is high and decreases when plasma Ca2+ is low. Thus, PTH secretion decreases and calcitonin release increases as serum calcium concentrations rise (Figure 48–6). The circulating concentrations of calcitonin are low, normally less than 15 and 10 pg/mL for males and females, respectively. The circulating t1/2 of calcitonin is about 10 min. Abnormally elevated levels of calcitonin are characteristic of thyroid C cell hyperplasia and MTC. The calcitonin gene is localized on human chromosome 11p and contains six exons; differential splicing of the exons leads to tissue-specific production of calcitonin, katacalcin, and CGRP.

Bone Physiology
The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

Bone Mass
Bone mineral density and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for about 60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium. Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. In women, loss of estrogen at menopause accelerates the rate of bone loss. Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficient calcium in all three areas, and deficiency of one is not compensated by excessive attention to another.

Bone Remodeling
Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called remodeling, by which bone mass is adjusted throughout adult life. Remodeling is carried out by myriad independent “bone-remodeling units” throughout the skeleton. In response to physical or biochemical signals, recruitment of narrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated
osteoclasts that resorb, or excavate, a cavity into the bone. Osteoclast production is regulated by osteoblast-derived cytokines (e.g., IL-1 and IL-6). One important mechanism is RANK and its natural ligand, RANKL (previously called osteoclast differentiation factor). On binding to RANK, RANKL induces osteoclast formation (Figure 48–7). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce OPG, which acts as a decoy ligand that inhibits osteoclast production by competing effectively with RANKL for binding to RANK. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK.

The resorption phase is followed by invasion of preosteoblasts into the base of the resorption cavity. These cells become osteoblasts and elaborate new bone matrix constituents that help form osteoid. Once the newly formed osteoid reaches a thickness of about 20 μM, mineralization begins. A complete remodeling cycle normally requires about 6 months. Small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary sufficiency, exercise, hormones, and drugs, affect bone balance.

Figure 48–6 Inverse relations between PTH and calcitonin release. As serum calcium falls below its set point of about 1.2 mM, PTH secretion increases as a means to defend calcium homeostasis. Conversely, as calcium levels rise, PTH secretion is inhibited, while release of calcitonin increases. (Replotted from original observations; Imanishi et al., 2002; Torres et al., 1991).

Abnormal Calcium Metabolism

Hypercalcemia

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrolithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption.

Hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTHrP is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue. PTHrP interacts with the PTHR in target tissues, thereby causing the hypercalcemia and hypophosphatemia seen in humoral hypercalcemia of malignancy (Grill et al., 1998). In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the tumor cells owing to stimulation of 25(OH) vitamin D–1α-hydroxylase.

Vitamin D excess may cause hypercalcemia if sufficient 25-OHD is present to stimulate intestinal Ca2+ hyperabsorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-OHD is diagnostic. Occasionally, patients with hyperthyroidism show mild hypercalcemia, presumably owing to increased bone turnover. Immobilization may lead to hypercalcemia in growing children and young adults but rarely causes hypercalcemia in older individuals unless bone turnover is already increased, as in Paget disease or hyperthyroidism. Hypercalcemia sometimes is noted in adrenocortical deficiency, as in Addison disease, or following removal of a hyperfunctional adrenocortical tumor. Hypercalcemia occurs following renal transplantation owing to persistent hyperfunctioning parathyroid tissue that resulted from the previous renal failure. Serum assays for PTH, PTHrP, and 25-OH- and 1,25-(OH)2D permit accurate diagnosis in the great majority of cases.

Hypocalcemia

Combined deprivation of Ca2+ and vitamin D, as observed with malabsorption states, readily promotes hypocalcemia. When caused by
malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mild hypocalcemia (i.e., serum Ca\(^{2+}\) in the range of 8–8.5 mg/dL [2–2.1 mM]), is usually asymptomatic. Patients exhibit greater symptoms if the hypocalcemia develops acutely.

Symptoms of hypocalcemia include tetany and related phenomena, such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic hyperparathyroidism, ectodermal changes (e.g., consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts) occur. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present. Hyperparathyroidism is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disease.

Disturbed Phosphate Metabolism

Dietary inadequacy rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (see Chapter 49). Osteomalacia is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the GI tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action. Hyperparathyphosasthemia occurs commonly in CKD. The increased phosphate level reduces the serum Ca\(^{2+}\) concentration, which in turn activates the parathyroid gland CaSR, stimulates PTH secretion, and exacerbates the hyperphosphatemia. The CaSR agonist cinacalcet suppresses PTH secretion and has been approved as treatment of secondary hyperparathyroidism in adult patients with CKD receiving chronic dialysis therapy, for hypercalcemia secondary to parathyroid cancer, and for primary hyperparathyroidism in patients unable to be managed surgically.

The investigational recombinant human monoclonal antibody KRN23 against FGF23 is extremely effective in correcting the hypophosphatemia associated with XLH, the most common form of hereditary rickets and osteomalacia. Monthly administration provides prolonged restoration of serum phosphate by reducing urinary phosphate excretion without adversely altering serum PTH or calcium levels (Carpenter et al., 2014; Imel et al., 2015). KRN23 was granted orphan drug status for treating XLH or other hypophosphatemic conditions in the E.U. in 2014, but it is not yet approved for use in the U.S.

Disorders of Vitamin D

Hyperparathyroidism

The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. In adults, hyperparathyroidism results from overtreatment of hyperparathyroidism and from faddist use of excessive doses. The amount of vitamin D necessary to cause hyperparathyroidism varies widely. As a rough approximation, continued daily ingestion of 50,000 units or more may result in poisoning. The initial signs and symptoms of vitamin D toxicity vary from mild symptoms such as emotional lability, anxiety, depression, and delusions to severe effects such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions.

Vitamin D Deficiency

Vitamin D deficiency results in inadequate absorption of Ca\(^{2+}\) and phosphate. The consequent decrease in plasma Ca\(^{2+}\) concentration stimulates PTH secretion, which acts to restore plasma Ca\(^{2+}\) at the expense of bone. FGF23 increases as well. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH and FGF23. In children, the result is failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as rickets.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalization of undermineralized bone matrix. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations less than 8 ng/mL are highly predictive of osteomalacia.

Metabolic Rickets and Osteomalacia

The disorders of metabolic rickets and osteomalacia are characterized by abnormalities in calcitriol synthesis or response. Variants include the following:

- **Hypophosphatemic vitamin D–resistant rickets:** Usually, this is an X-linked disorder (XLH) of calcium and phosphate metabolism. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate.
- **Vitamin D–dependent rickets:** of type I: Also called VDDR-1 or PDDR: This is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol due to mutations in CYP1a (1a-hydroxylase).
- **Vitamin D–dependent rickets:** of type II: This is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Multiple heterogeneous mutations of the VDR cause this variant.
- **CKD-MBD (renal rickets):** Refers to the disordered bone morphology that attends CKD. The variant is characterized by abnormalities of bone turnover, mineralization, volume, linear growth, or strength, as well as underlying defects in mineral ion, PTH, or vitamin D metabolism.

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Many women (30%–50%) and men (15%–30%) suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age, and spine and hip fractures are associated with reduced survival.

Osteoporosis can be categorized as primary or secondary. *Primary osteoporosis* represents two different conditions: *type I osteoporosis*, characterized by loss of trabecular bone owing to estrogen lack at menopause, and *type II osteoporosis*, characterized by loss of cortical and trabecular bone in men and women due to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. *Secondary osteoporosis* is due to systemic illness or chronic use of medications such as glucocorticoids or phenytoin. The most successful approaches to secondary osteoporosis are prompt resolution of the underlying cause and drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used in both conditions.

Paget Disease

Single or multiple sites of disordered bone remodeling characterize Paget disease. It affects up to 2%–3% of the population more than 60 years of age. The primary pathologic abnormality is increased bone resorption followed by exuberant bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget disease.

Chronic Kidney Disease–Mineral Bone Disease

Bone disease is a frequent consequence of CKD and dialysis treatment. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa),
Hypercalcemia can be life threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6–8 L/d). Agents that augment Ca\(^{2+}\) excretion, such as loop diuretics (see Chapter 25), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted.

Calcium may be useful in managing hypercalcemia. Reduction in Ca\(^{2+}\) can be rapid, although “escape” from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 h; if there is no response within 1–2 days, the dose may be increased to a maximum of 8 units/kg every 12 h. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 h.

Calcitonin can lower serum calcium by 1–2 mg/dL.

Calcium gluconate can be intravenously given by slow injection (a 22% solution; 18 mg or 0.9 mEq of Ca\(^{2+}\)/mL). The rate of injection should be slow (not more than 1 mL/min) to prevent cardiac arrhythmias from a high concentration of Ca\(^{2+}\). The injection may induce a moderate fall in blood pressure owing to vasodilation. Calcium gluconate injection (a 10% solution; 9.3 mg of Ca\(^{2+}\)/mL) given intravenously is the treatment of choice for severe hypercalcemic tetany. Patients with moderate-to-severe hypercalcemia are typically treated by intravenous infusion of calcium gluconate at a dose of 10–15 mg of Ca\(^{2+}\)/kg of body weight over 4–6 h. Because the usual 10-mL vial of a 10% solution contains only 93 mg Ca\(^{2+}\), many vials are needed. Treatment with intravenous Ca\(^{2+}\), administered as calcium gluconate (10–30 mL of a 10% solution), also may be lifesaving in patients with extreme hyperkalemia (serum K\(^{+}\) > 7 mEq/L).

Additional FDA-approved uses of intravenous Ca\(^{2+}\) include treatment of black widow spider envenomation and management of magnesium toxicity. The intramuscular route should not be employed because absccess formation at the injection site may result.

For control of milder hypercalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium carbonate is relatively inexpensive and well tolerated, so it is prescribed most frequently. Calcium carbonate and calcium acetate are used to restrict phosphate absorption in patients with CKD and oxalate absorption in patients with inflammatory bowel disease.

**Vitamin D**

The physiology and corresponding mechanism of action of vitamin D was described previously in this chapter.

**ADME**

Vitamin D is absorbed from the small intestine. Bile is essential for adequate absorption of vitamin D and is also the primary route of vitamin D excretion. Patients who have intestinal bypass surgery or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption. Absorbed vitamin D circulates in the blood in association with vitamin D–binding protein. The vitamin disappears from plasma with a \(t_{1/2}\) of 20–30 h but is stored in fat depots for prolonged periods.

**Therapeutic Uses for Vitamin D**

The major therapeutic uses of vitamin D are the following:

- prophylaxis and cure of nutritional rickets
- treatment of metabolic rickets and osteomalacia, particularly in the setting of CKD
- treatment of hypoparathyroidism
- prevention and treatment of osteoporosis
- dietary supplementation

**Nutritional Rickets.** Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The incidence of this condition in the U.S. is now increasing. Infants and children receiving adequate amounts of vitamin D–fortified food do not require additional vitamin D; however, breastfed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement (see Table 48–1) (Wagner et al., 2008), usually administered with vitamin A, for which purpose a number of balanced vitamin A and D preparations are available.

Because the fetus acquires more than 85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D. Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca\(^{2+}\) and phosphate concentrations in about 10 days, with radiographic evidence of healing in about 3 weeks. However, a larger dose of 3000–4000 units daily often is prescribed for more rapid healing, particularly when severe thoracic rickets compromises respiration.

**Treatment of Osteomalacia and CKD-MBD.** Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with CKD are at risk for developing osteomalacia but also may develop a complex bone disease called CKD-MBD, formerly known as renal osteodystrophy. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in vitamin D metabolism.
bone mineralization that is due to decreased renal synthesis of calcitriol. In CKD-MBD, low BMD may be accompanied by high-turnover bone lesions, typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease.

The therapeutic approach to the patient with CKD-MBD depends on its skeletal manifestation. In high-turnover (hyperparathyroidy) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended. Administration of calcium-containing phosphate binders along with calcitriol may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease. The increased calcium burden associated with calcium-based phosphate binders likely contributes to the increased incidence of vascular calcification in patients with CKD.

Non–calcium-containing phosphate binders are highly effective alternatives to traditional calcium-based agents. Sevelamer hydrochloride is a nonabsorbable polymer that acts as a nonselective ion exchanger. The drug is modestly water soluble, and only trace amounts are absorbed from the GI tract. Sevelamer not only effectively lowers serum phosphate concentration in hemodialysis patients but also binds bile acids, and to a lesser extent low-density lipoprotein cholesterol and 1a-soluble vitamins. Side effects of sevelamer hydrochloride include vomiting, nausea, diarrhea, dyspepsia, and metabolic acidosis.

Sevelamer carbonate is equivalent to sevelamer hydrochloride in terms of safety and tolerability, with a lower likelihood of inducing metabolic acidosis. Lanthanum carbonate is a poorly permeable trivalent cation that is highly effective in treating the hyperphosphatemia associated with CKD-MBD but is associated with GI side effects.

Most recently, the FDA approved two novel iron-based phosphate binders. Sucroferric oxyhydroxide is a multinuclear iron(III)–oxyhydroxide compound that binds phosphate by ligand exchange. The drug exhibits similar phosphate control efficacy as sevelamer with a lower daily pill burden. Ferric citrate also exhibits comparable phosphate control efficacy to sevelamer and to calcium acetate. In addition, ferric citrate delivers a significant amount of iron, resulting in increased erythropoietic parameters and the possibility of iron overload with chronic dosing. Diarrhea is a common side effect of both iron-based phosphate binders (Shah et al., 2015).

Niacin and nicotinic acid lower serum phosphate and have been proposed as alternatives to the use of sevelamer. Recent studies suggested that extended-release niacin does not improve cardiovascular outcomes and is associated with greater all-cause mortality. Direct comparison of nicotinic acid and sevelamer in patients with CKD showed that although nicotinic acid reduced hyperphosphatemia, sevelamer exhibited greater efficacy in controlling hyperphosphatemia as well as the Ca × P product (Ahmadi et al., 2012; Kalil et al., 2015).

**Hyypoparathyroidism.** Vitamin D and its analogues are the mainstay of the therapy of hypoparathyroidism. DHT, a reduced form of vitamin D₃, has a faster onset, shorter duration of action, and greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent; however, it is no longer available in the U.S. Although most hypoparathyroid patients respond to any form of vitamin D, calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

**Prevention and Treatment of Osteoporosis.** This is described separately further in the chapter.

**Dietary Supplementation.** See Table 48–1.

**Adverse Effects of Vitamin D Therapy**

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal absorption of Ca²⁺ and phosphate, along with the potential to mobilize osseous Ca⁺⁺ and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. Non–calcemic vitamin D analogues provide alternative interventions, although they do not obviate the need to monitor serum Ca⁺⁺ and phosphorus concentrations. Hypercalcitrinosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support; forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca²⁺ concentration falls to normal, and Ca²⁺ in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless kidney damage has been severe.

**Available Vitamin D Analogues**

*Cochleciferol* (vitamin D₁) and calcitriol (1,25-dihydroxycholecalciferol) are available for oral administration or injection. Several derivatives of vitamin D are also used therapeutically.

**Doxercalciferol** (1a-hydroxyvitamin D₃), a prodrug that first must be activated by hepatic 25-hydroxylation, is approved for use in treating secondary hyperparathyroidism. **DHT** is a reduced form of vitamin D₃. In the liver, DHT is converted to its active form, 25-OH dihydrotracalcalciferol. DHT is effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca²⁺ in hypoparathyroidism. DHT is well absorbed from the GI tract and maximally increases serum Ca²⁺ concentration after 2 weeks of daily administration. The hypercalciemic effects typically persist for 2 weeks but can last twice that long. DHT (not marketed in the U.S.) is available for oral administration in doses ranging from 0.2 to 1 mg/d (average 0.6 mg/d).

**Ergocalciferol** (calciferol) is vitamin D₂. It is available for oral administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D–resistant rickets type II, typically in doses of 50,000–200,000 units/d in conjunction with calcium supplements. **1a-Hydroxycholecalciferol** (1-OHD₃, alfalcacidol) is a synthetic vitamin D₃ derivative that is already hydroxylated in the 1α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH)₂D₃. It is equivalent to calcitriol in assays for stimulation of intestinal absorption of Ca²⁺ and bone mineralization; it does not require renal activation. It is available in the U.S. for experimental purposes.

**Analogues of Calcitriol.** Several vitamin D analogues suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism. **Calcipotriene** (Calcipotriol). Calcipotriol is a synthetic derivative of calcitriol with a modified side chain. Calcipotriol is less than 1% as active as calcitriol in regulating Ca²⁺ metabolism. Calcipotriol has been studied extensively as a treatment of psoriasis and is available for topical use (see Chapter 70).

**Paricalcitol.** Paricalcitol (1,25-dihydroxy-19-norvitamin D₃) is a synthetic calcitriol derivative that lacks the exocyclic C₁₉ and has a vitamin D₃ side chain. It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Mazzaferro et al., 2014). Paricalcitol administered orally or intravenously is FDA-approved for treating secondary hyperparathyroidism in patients with CKD.

**Maxacalcitol.** Known variously as 1,25-dihydroxy-22-oxavitamin D₃, OCT, and 22-oxacalcitriol, maxacalcitol differs from calcitriol only in the substitution of C-22 with an O atom. Oxacalcitriol has a low affinity for vitamin D–binding protein; thus, more of the drug circulates in the free (unbound) form and is metabolized more rapidly than calcitriol, with a consequent shorter t½. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in CKD. Oxacalcitriol is not available in the U.S.

**Calcitonin**

**Mechanism of Action**

The CTR, a GPCR that couples to multiple G proteins, mediates calcitonin’s actions. The hypercalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption (Henriksen et al., 2010). The calcitonin peptide family also includes CGRP, the closely related peptide adrenomedullin, intermedin, and amylin. CGRP and adrenomedullin are potent endogenous vasodilators.
Bisphosphonates

Chemistry

Bisphosphonates are analogues of pyrophosphate that contain two phosphonate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate (Figure 48-8). These agents form a three-dimensional structure capable of chelating divalent cations such as Ca²⁺ and have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. First-generation bisphosphonates (medronate, clodronate, and etidronate) contain minimally modified side chains or possess a chlorophenol group (tiludronate) and are the least-potent agents. Second-generation aminobisphosphonates (e.g., alendronate and pamidronate) contain a nitrogen atom in the side chain and are 10–100 times more potent than first-generation compounds. Third-generation bisphosphonates (e.g., risedronate and zoledronate) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents (Ebertino et al., 2011).

Mechanism of Action

Bisphosphonates act by direct inhibition of bone resorption. Bisphosphonates concentrate at sites of active remodeling, remain in the matrix until the bone is remodeled, and then are released in the acid environment of the resorption lacunae and induce apoptosis in osteoclasts. Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physiochemical effects (Cremers and Papapoulos, 2011). The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

ADME

All oral bisphosphonates are poorly absorbed from the intestine. They have remarkably limited bioavailability (<1% [alendronate, risedronate] to 6% [etidronate, tiludronate]), which is further reduced by food and medications containing divalent cations such as calcium supplements, antacids, and iron. Hence, these drugs should be administered with a full glass of water following an overnight fast and at least 30 min before breakfast. Bisphosphonates distribute extensively into bone, undergo negligible hepatic clearance, and are excreted unchanged by the kidneys. Renal excretion of bisphosphonates declines proportionally with kidney function, and they are not recommended for patients with a creatinine clearance of less than 30 mL/min (Cremers and Papapoulos, 2011; Ott, 2015).

Therapeutic Uses

Bisphosphonates are used extensively in conditions characterized by osteoclast-mediated bone resorption, including Paget disease, tumor-associated osteolysis, and hypercalcemia. In particular, much interest is focused on the role of bisphosphonates in the treatment of osteoporosis, including postmenopausal osteoporosis and steroid-induced osteoporosis. Clinical trials showed that treatment is associated with increased BMD and protection against fracture. Bisphosphonates may also have direct antitumor action by inhibiting oncogene activation through their antiangiogenic effects. Randomized clinical trials of bisphosphonates in patients with breast cancer suggested that these agents delay or prevent development of metastases as a component of endocrine adjuvant therapy (Early Breast Cancer Trialists’ Collaborative, 2015). Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Adverse Effects

Oral bisphosphonates can cause heartburn, esophageal irritation, or esophagitis. Other GI side effects include abdominal pain and diarrhea. Symptoms often abate when patients take the medication after an overnight fast, with tap or filtered water (not mineral water), and remain upright. Patients with active upper GI disease should not be given oral bisphosphonates. Initial parenteral infusion of pamidronate may cause skin flushing, flu-like symptoms, muscle and joint aches and pains, nausea and vomiting, abdominal discomfort, and diarrhea (or constipation) but mainly when given in higher concentrations or at faster rates than those recommended. These symptoms are short lived and generally do not recur with subsequent administration.

Zoledronate can cause severe hypocalcemia and has been associated with renal toxicity, deterioration of kidney function, and potential kidney disease. Infusion of zoledronate, 4 mg, should be performed over at least 15 min; patients should have standard laboratory and clinical parameters of kidney function assessed prior to treatment and periodically thereafter to monitor for deterioration in kidney function. Bisphosphonate use also is associated with osteonecrosis of the jaw (a rare event, with an incidence of ~ 2 in 100,000 patient-years in which the precise causal role of bisphosphonates has not been elucidated) as well as stress fractures in the lateral cortex of the femoral shaft (most commonly associated with alendronate and rarely with zoledronate; Reid, 2015).

Available Bisphosphonates

Etidronate sodium is used for treatment of Paget disease and may be used parenterally to treat hypercalcemia (although largely supplanted for this use by amidronate and zoledronate). Pamidronate (available in the U.S. only for parenteral administration) is approved for management of hypercalcemia associated with malignancy and Paget disease and for prevention of bone loss in breast cancer and multiple myeloma; it also is effective in other skeletal disorders. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60–90 mg over 2–24 h.

Several newer bisphosphonates have been approved for treatment of Paget disease. These include tiludronate, alendronate, and risedronate.

Figure 48-8 Pyrophosphate and bisphosphonates. The substituents (R₁ and R₂) on the central carbon of the bisphosphonate parent structure are shown in blue. Examples of a first-generation bisphosphonate (medronate), a second-generation aminobisphosphonate (alendronate), and a third-generation bisphosphonate (zoledronate) are shown.
Tiludronate standard dosing is 400 mg/d orally for 3 months. Tiludronate in recommended doses does not interfere with bone mineralization, unlike etidronate. Zoledronate is approved for treating Paget disease; administered as a single 5-mg infusion, zoledronate decreases bone turnover markers for 6 months with no loss of therapeutic effect. Zoledronate is widely used for prevention of osteoporosis in patients with prostate and breast cancer receiving hormonal therapy. It reduces both vertebral and nonvertebral fractures. A 4-mg formulation is available for intravenous treatment of hypercalcemia of malignancy, multiple myeloma, or bone metastasis resulting from solid tumors. The potent bisphosphonate ibandronate is approved for the prevention and treatment of postmenopausal osteoporosis. The recommended oral dose is 2.5 mg daily or 150 mg once monthly.

For patients in whom oral bisphosphonates cause severe esophageal distress, intravenous zoledronate and ibandronate offer skeletal protection without causing adverse GI effects. For treatment of osteoporosis, ibandronate (3 mg) is given intravenously every 3 months. Zoledronate is the first bisphosphonate to be approved for once-yearly intravenous treatment of osteoporosis (5 mg annually).

Parathyroid Hormone
Continuous administration of PTH or high-circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, intermittent PTH administration promotes bone growth. Although hypoparathyroidism was the last classic endocrine-deficiency disease to have the missing hormone as an available treatment option, PTH analogues are now available to these patients.

Chemistry
As described previously, PTH is a single-polypeptide chain of 84 amino acids with a molecular mass of about 9300 Da. The classic biological activity of PTH is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTHR and hormone activity. Currently available PTH analogues include teriparatide, a synthetic human 34–amino acid amino-terminal PTH fragment [hPTH(1–34)]; a full-length replica of endogenous PTH, recombinant human PTH consisting of 84 amino acids [rhPTH(1–84)] (Kim and Keating, 2015); and abaloparatide, a recently approved synthetic 34-amino acid analogue of human PTHrP, hPTHrP(1–34).

Mechanism of Action
The physiological functions and mechanism of action of PTH were described previously in the chapter.

ADME
These agents are peptides and are administered by subcutaneous injection (see Drugs Available). Pharmacokinetics and systemic actions of teriparatide on mineral metabolism are the same as for PTH. Serum PTH concentrations peak at 30 min after the injection and are undetectable within 3 h, whereas the serum Ca\(^{2+}\) concentration peaks at 4–6 h after administration. Teriparatide bioavailability averages 95%. The drug’s volume of distribution is approximately 0.1 L/kg. The elimination of teriparatide proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion. Teriparatide systemic clearance averages 62 L/h in women and 94 L/h in men. The elimination t\(_{1/2}\) of serum teriparatide is about 1 h when administered subcutaneously versus 5 min when administered intravenously.

Abaloparatide is supplied in an injector pen with 30 daily doses. The peptide is rapidly absorbed (bioavailability = 36%), achieving peak concentrations ~30 min following subcutaneous injection. Elimination half-life is ~1.7 h; clearance is presumed to be by proteolytic hydrolysis, with renal elimination of peptide fragments.

For rhPTH(1–84), dose-proportional increases in serum Ca\(^{2+}\) concentration, which peaks at 10–12 h after subcutaneous administration, are exhibited. Bioavailability of rhPTH(1–84) is 53%, and its volume of distribution is 5.3 L. The liver and the kidneys are the major route of rhPTH(1–84) elimination, as for teriparatide. The elimination t\(_{1/2}\) of rhPTH(1–84) is ~3 h (Clarke et al., 2014; Kim and Keating, 2015). Overall, the prolonged peak effects and slower elimination of rhPTH(1–84) compared to teriparatide may explain why teriparatide typically requires multiple injections per day while rhPTH(1–84) requires only single-daily or alternate-day dosing.

Therapeutic Uses
Teriparatide (PTH1–34) and abaloparatide (PTHrP(1–34)) are the only anabolic agents currently available that increase new bone formation. They are approved for use in treating severe osteoporosis in patients at a high risk for fracture. In postmenopausal women with osteoporosis, teripar-}
A novel class of drugs that inhibit the CaSR (calcilytics) stimulate the secretion of PTH and decrease renal excretion of Ca\(^{2+}\). The calcillicyteronacaleret, investigated for potential treatment of postmenopausal osteoporosis, was less effective than teriparatide, and its development was subsequently halted (Fitzpatrick et al., 2012). The role of calcilytics in the treatment of diseases involving hypocalcemia or hypercalcemia continues to be explored (Nemeth and Shoback, 2013).

**Calcium-Sensing Receptor Mimetics**

Calcimetics are drugs that mimic the stimulatory effect of Ca\(^{2+}\) on the CaSR to inhibit PTH secretion by the parathyroid glands. Cinacalcet, the first and only approved drug in the class currently, offers a pharmacotherapeutic alternative to surgery for the treatment of PTH hypersecretion diseases.

**Chemistry**

Cinacalcet is available as a hydrochloride (Figure 48–9) and is formulated with one chiral center having an R-absolute configuration; the R-enantiomer is the more potent enantiomer and is primarily responsible for cinacalcet’s pharmacodynamic activity.

**Mechanism of Action**

By enhancing the sensitivity of the CaSR to extracellular Ca\(^{2+}\), calcimetics lower the concentration of Ca\(^{2+}\) at which PTH secretion is suppressed. Inorganic di- and trivalent cations, along with polycations such as aminoglycosides (e.g., streptomycin, gentamicin, and neomycin) and polybasic amino acids (e.g., polylysine) are full agonists and are referred to as type I calcimimetics. They are able to activate the CaSR directly with no other cofactors. On the other hand, phenylalkylamine derivatives, including cinacalcet, that are allosteric CaSR modulators require the presence of Ca\(^{2+}\) or other full agonists to enhance the sensitivity of activation without altering the maximal response and are designated type II calcimimetics (Cianferotti et al., 2015; Filopanti et al., 2013).

**ADME**

Cinacalcet exhibits first-order absorption, with peak serum concentrations achieved 2–6 h after oral administration. Maximal effects on serum PTH occur 2–4 h after administration. It has an extraordinarily large volume of distribution of 1000 L and is metabolized by multiple hepatic CYPs, including CYPs 3A4, 2D6, and 1A2. Metabolites are eliminated by biliary (15%) and renal excretion (85%). Cinacalcet has an elimination half-life of 30–40 h.

**Therapeutic Uses**

Cinacalcet is approved for the treatment of (1) secondary hyperparathyroidism in adults with CKD on dialysis; (2) hypercalcemia in adults with parathyroid carcinoma; and (3) hypercalcemia in adult patients with primary hyperparathyroidism who are not candidates for surgical parathyroidectomy. Treatment with cinacalcet lowers serum PTH levels in patients with normal or reduced kidney function (Nemeth and Shoback, 2013). In patients with secondary hyperparathyroidism on dialysis, treatment with cinacalcet significantly decreases bone turnover and improves bone histology (Behets et al., 2015). Moreover, by lowering serum FGF23 concentrations, cinacalcet treatment decreases the rate of cardiovascular death and major cardiovascular events (Moe et al., 2015).

**Adverse Effects**

The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum [Ca\(^{2+}\)] is less than 8.4 mg/dL; serum Ca\(^{2+}\) and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy and after changing dosage. Seizure threshold is lowered by significant reductions in serum Ca\(^{2+}\); therefore, patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is less than 100 pg/mL, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL.

**Drug Interactions**

Drug interactions can be anticipated with drugs that interfere with Ca\(^{2+}\) homeostasis or that hinder cinacalcet absorption. Potentially interfering drugs include vitamin D analogues, phosphate binders, bisphosphonates, calcitriol, glucocorticoids, gallium, and cisplatin. Caution is recommended when cinacalcet is coadministered with strong inhibitors of CYP3A4 (e.g., ketoconazole, erythromycin, or itraconazole). Because cinacalcet is a strong inhibitor of CYP2D6, dose adjustment may be required for concomitant medications that are CYP2D6 substrates (e.g., many β adrenergic receptor blockers, flecaïnine, vinblastine, and most tricyclic antidepressants).

**Fluoride**

Fluoride is discussed because of its effects on dentition and bone and its toxic properties.

**Mechanism of Action**

Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts. However, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or others. Fluoride can inhibit several enzyme systems and diminish tissue respiration and anaerobic glycolysis.

**ADME**

Fluoride is obtained from the ingestion of plants and water, with absorption taking place largely in the intestine. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure. Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone. The kidneys are the major sites of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions.

**Therapeutic Use**

Because it is concentrated in the bone, the radionuclide \(^{18}F\) has been used in skeletal imaging. Sodium fluoride is a mainstay of therapy for the prevention of dental carries.

**Fluoride and Dental Caries**

Supplementation of water fluoride content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth. There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of fluoride solutions by dental personnel appears to be effective on newly erupted teeth and can reduce the incidence of caries by 30–40%. Dietary fluoride supplements should be considered for children less than 12 years of age whose drinking water contains less than 0.7 ppm fluoride. Adequate incorporation of fluoride into teeth hardens the outer layers of enamel and increases resistance to demineralization. The fluoride salts usually employed in dentifrices are sodium fluoride and...
stannous fluoride. Sodium fluoride also is available in a variety of preparations for oral and topical use.

Regulation of the fluoride concentration of community water supplies periodically encounters vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water.

**Acute Poisoning**

Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the CNS consistent with the Ca\(^{2+}\)-binding effect of fluoride and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for humans is about 5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with limewater (0.15% calcium hydroxide solution) or other Ca\(^{2+}\) salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

**Chronic Poisoning**

In humans, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described more than 60 years ago. In very mild molting, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown–to-black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Molting is one of the first visible signs of excess fluoride intake during childhood. Continuous use of water containing about 1 ppm of fluoride may result in very mild molting in 10% of children; at 4–6 ppm, the incidence approaches 100%, with a marked increase in severity. Severe dental fluorosis formerly occurred in regions where local water supplies had a very high fluoride content (e.g., Pompeii, Italy, and Pike’s Peak, CO). Current regulations in the U.S. require lowering the fluoride content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a fluoride content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time.

---

**Figure 48–10** Relative efficacy of different therapeutic interventions on BMD of the lumbar spine. Teriparatide (40 μg) (Neer et al., 2001), PTH (25 μg) + estradiol, alendronate (10 mg), estradiol (0.625 mg/d), raloxifene (120 mg), calcitonin (200 IU). Typical results with placebo treatment underscore the inexcusable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made.

---

**Antiresorptive Agents**

**Bisphosphonates**

Bisphosphonates are the most frequently used drugs for the prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates, alendronate and risedronate, have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization. Alendronate, risedronate, and ibandronate are used for prevention and treatment of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis.

**Denosumab**

The ligand of RANK binds to its cognate receptor RANK on the surface of precursor and mature osteoclasts and stimulates these cells to mature and resorb bone. OPG, which competes with RANK for binding to RANKL, is the physiological inhibitor of RANKL. Denosumab is a human monoclonal antibody that binds with high affinity to RANKL, mimicking the effect of OPG and thereby reducing the binding of RANKL to RANK. Denosumab blocks osteoclast formation and activation. It increases BMD and decreases bone turnover markers when given subcutaneously, 60 mg once every 6 months. Osteonecrosis of the jaw and fractures of the femoral shaft have been reported with denosumab use. It is contraindicated in the setting of preexisting hypocalcemia.
Selective Estradiol Receptor Modulators

Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. Raloxifene acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an antiestrogen on the breast (see Chapter 44). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and reduces the risk of vertebral compression fracture (Komm and Mirkin, 2014). Raloxifene is approved for both the prevention and the treatment of osteoporosis. Adverse effects of raloxifene include worsening of vasomotor symptoms. The drug is also associated with an increased risk of deep vein thrombosis and pulmonary embolism, so it is contraindicated in adults with a history of venous thromboembolism.

Estrogen

Postmenopausal status or estrogen deficiency at any age significantly increases a patient’s risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (see Chapter 44). However, the Women’s Health Initiative studies indicated that HRT significantly increases risks of heart disease and breast cancer; consequently, HRT is now reserved only for the short-term relief of vasomotor symptoms associated with menopause.

Calcium

The rationale for using supplemental calcium to protect bone varies with time of life. For preteens and adolescents, adequate substrate calcium is required for bone accretion. Higher Ca$^{2+}$ intake during the third decade of life is positively related to the final phase of bone acquisition. There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. In elderly subjects, supplemental calcium suppresses bone turnover and improves BMD. Patients may increase calcium by dietary means and may choose from many palatable, low-cost calcium preparations. The most frequently prescribed is carbonate, which should be taken with meals to facilitate dissolution and absorption. Traditional dosing of calcium is about 1000 mg/d, nearly the amount present in a quart of milk. Adults more than 50 years of age need 1200 mg of calcium daily. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of 2000 mg or more are frequently reported to be constipating.

Vitamin D and Its Analogues

Modest supplementation with vitamin D (400–800 IU/d) may improve intestinal Ca$^{2+}$ absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. Supplemental vitamin D in combination with calcium reduces fracture incidence.

The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Higher doses of calcitriol appear to be more likely to improve BMD, but at the risk of developing hypercalcemia and hypercalcuria; therefore, close scrutiny of patients and dose are required. Restriction of dietary calcium may reduce toxicity during calcitriol therapy.

Calcitonin

Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis, most prominently in patients with high intrinsic rates of bone turnover. Calcitonin nasal spray (200 units/d) reduces the incidence of vertebral compression fractures by about 40% in osteoporotic women (Chesnut et al., 2000).

Thiazide Diuretics

Although not strictly antiresorptive, thiazides reduce urinary Ca$^{2+}$ excretion and constrain bone loss in patients with hypercalcemia. Hydrochlorothiazide, 25 mg once or twice daily, may reduce urinary Ca$^{2+}$ excretion substantially. Effective doses of thiazides for reducing urinary Ca$^{2+}$ excretion generally are lower than those necessary for blood pressure control (see Chapters 25 and 28).

Anabolic Agents

Teriparatide

Teriparatide is the only anabolic agent currently available that increases new bone formation. It is FDA-approved for treatment of osteoporosis for up to 2 years in both men and postmenopausal women at high risk for fractures. Teriparatide increases predominantly trabecular bone at the lumbar spine and femoral neck; it has less-significant effects at cortical sites. Teriparatide is approved at the 20-mcg dose, administered once daily by subcutaneous injection in the thigh or abdominal wall. The most common adverse effects associated with teriparatide include injection-site pain, nausea, headaches, leg cramps, and dizziness.

Combination Therapies

Osteoporosis

Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men. Sequential treatment with PTH(1–84) followed by alendronate increases vertebral BMD to a greater degree than alendronate or estrogen alone.

Paget Disease

Although most patients with Paget disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective.

Optimal therapy for Paget disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate exhibits greater response rates and a longer median duration of complete response. Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects.

HORMONES AND HORMONE ANTAGONISTS

**Miscellaneous Antiresorptive Agents**

**Calcitonin**
- Paget disease
- Hypercalcemia
- Postmenopausal osteoporosis
- Direct inhibitor of osteoclastic bone resorption
- Anaphylaxis/hypersensitivity reported

**Denosumab**
- Treatment and prevention of osteoporosis
- Treatment to increase bone mass in adults at high risk for fracture receiving cancer therapy
- Human monoclonal antibody that binds with high affinity to RANKL
- Contraindicated in setting of preexisting hypocalcemia
- Osteonecrosis of the jaw reported
- Fractures of the femoral shaft reported

**Raloxifene**
- Treatment and prevention of osteoporosis
- Selective estrogen receptor modulator
- Contraindicated in adults with history of venous thromboembolism; increased risk of deep vein thrombosis and pulmonary embolism

**Hydrochlorothiazide**
- Osteoporosis
- Hypercalciuria
- Reduce urinary calcium excretion
- Contraindicated in adults with history of venous thromboembolism; increased risk of deep vein thrombosis and pulmonary embolism

**Fluoride**
- Prophylaxis of dental caries
- Childhood consumption of fluoridated drinking water reduces incidence of caries in permanent teeth
- Topical application can reduce the incidence of caries by 30%–40%

Gastrointestinal Pharmacology

Chapter 49. Pharmacotherapy for Gastric Acidity, Peptic Ulcers, and Gastroesophageal Reflux Disease / 909
Chapter 50. Gastrointestinal Motility and Water Flux, Emesis, and Biliary and Pancreatic Disease / 921
Chapter 51. Pharmacotherapy of Inflammatory Bowel Disease / 945
Gastric acid and pepsin in the stomach normally do not produce damage or symptoms of acid-peptic diseases because of intrinsic defense mechanisms. The stomach is protected by a number of factors, collectively referred to as “mucosal defense,” many of which are stimulated by the local generation of PGs and NO. If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of acid-related disorders are accomplished by decreasing gastric acidity and enhancing mucosal defense. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases revolutionized approaches to prevention and therapy of these common disorders.

Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the tone of the lower esophageal sphincter, and stimulating esophageal motility (see Chapter 50).

### Physiology of Gastric Secretion

Gastric acid secretion is a complex and continuous process: Neuronal (ACh, GRP); paracrine (histamine); and endocrine (gastrin) factors regulate the secretion of H⁺ by parietal cells (acid-secreting cells) (Figure 49–1). Their specific receptors (M₁, BB₁, H₂, and CCK₂, respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach. Some of these receptors are also present on ECL cells, where they regulate the release of histamine. The H₂ receptor is a GPCR that activates the Gₛ–adenyl cyclase–cyclic AMP–PKA pathway (see Chapters 3 and 39). ACh and gastrin signal through GPCRs that couple to the Gₛ–PLC–IP₃–Ca²⁺ pathway in parietal cells; GRP uses the same signaling pathway to activate gastrin secretion from G cells. In parietal cells, the cyclic AMP and the Ca²⁺-dependent pathways activate H⁺,K⁺-ATPase (the proton pump), which exchanges H⁺ and K⁺ across the parietal cell membrane. This pump generates the largest ion gradient known in vertebrates, with an intracellular pH of about 7.3 and an intracanicular pH of about 0.8.

The important structures for CNS stimulation of gastric acid secretion are the dorsal motor nucleus of the vagal nerve, the hypothalamus, and the solitary tract nucleus. Efferent fibers originating in the dorsal motor nuclei descend to the stomach via the vagus nerve and synapse with ganglion cells of the enteric nervous system. ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M₁ receptors on the basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the enteric nervous system via ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the “cephalic” phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the ECL cells in the fundus of the stomach and of gastrin from G cells in the gastric antrum.

The ECL cells, the source of gastric histamine, are usually in close proximity to parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H₂ receptors to stimulate gastric acid secretion.

*Gastrin*, produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin release, including CNS activation, local distention, and chemical components of the gastric contents. In addition to releasing ACh, some vagal fibers to the stomach also release GRP (a peptide of 27 amino acids): GRP activates the BB₂ bombesin receptor on G cells, activating the Gₛ–PLC–IP₃–Ca²⁺ pathway and causing secretion of gastrin. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role.

Somatostatin, produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to less than 3 stimulates somatostatin release, which in turn suppresses gastrin release in a negative-feedback loop. Somatostatin-producing cells are decreased in patients with *H. pylori* infection, and the consequent reduction of somatostatin’s inhibitory effect may contribute to excess gastrin production.
Parietal Cell H⁺,K⁺-ATPase

H⁺,K⁺-ATPase is the enzyme responsible for secreting protons into the lumen of the gastric gland (Shin et al., 2009). It is a heterodimeric protein composed of two subunits that are the products of two genes. The ATP4A gene encodes the α subunit that contains the catalytic sites of the enzyme and forms the membrane pore, and the ATP4B encodes the β subunit of the H⁺,K⁺-ATPase, which contains an N-terminal cytoplasmic domain, a transmembrane domain, and a highly glycosylated extracellular domain. Hydronium ions bind to three active sites present in the α subunit, and secretion involves conformational change that allows the movement of protons. This movement is balanced by the transport of K⁺. The stoichiometry of transport is pH dependent, varying between two H⁺ and two K⁺ per molecule of ATP to one of each under more acidic conditions. Inhibiting the H⁺,K⁺-ATPase (or proton pump) is the mainstay of modern pharmacotherapy for acid-related disorders.

Gastric Defenses Against Acid

The extremely high concentration of H⁺ in the gastric lumen requires robust defense mechanisms to protect the esophagus, stomach, and proximal small intestine (Wallace, 2008). The primary esophageal defense is the gastroesophageal junction—the lower esophageal sphincter in association with the diaphragm and angle of His—which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms that require adequate mucosal blood flow. One key defense is the secretion of a mucous layer that helps to protect gastric epithelial cells by trapping secreted bicarbonate at the cell surface. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by PGs E₂ and I₁, which also directly inhibit gastric acid secretion by parietal cells. Thus, drugs that inhibit PG formation (e.g., NSAIDs, ethanol) decrease mucus secretion and predispose to the development of acid-peptic disease. The proximal part of the duodenum is protected from gastric acid through the production of bicarbonate, primarily from mucosal Brunner glands.

Abbreviations

ACh: acetylcholine  
cAMP: cyclic adenosine monophosphate  
CCK: cholecystokinin  
CNS: central nervous system  
CYP: cytochrome P450  
DU: duodenal ulcer  
ECG: electrocardiogram  
ECI: enterochromaffin-like cell  
ENS: enteric nervous system  
GERD: gastroesophageal reflux disease  
GI: gastrointestinal  
GPCR: G protein–coupled receptor  
GRP: gastrin-releasing peptide  
GU: gastric ulcer  
HIST: histamine  
IP: i: inositol 1,4,5-trisphosphate  
NO: nitric oxide  
NSAID: nonsteroidal anti-inflammatory drug  
OTC: over the counter  
PG: prostaglandin  
PK: protein kinase  
PLC: phospholipase C  
PPI: proton pump inhibitor  
SST: somatostatin

Proton Pump Inhibitors

The most potent suppressors of gastric acid secretion are inhibitors of the gastric H⁺,K⁺-ATPase or proton pump (Figure 49–2). These drugs diminish the daily production of acid (basal and stimulated) by 80%–95% (Shin and Sachs, 2008).

Mechanism of Action and Pharmacology

Six PPIs are available for clinical use: omeprazole and its S-isomer, esomeprazole, lansoprazole and its R-enantiomer, dexlansoprazole, rabeprazole, and pantoprazole. All PPIs have equivalent efficacy at comparable doses.

Proton pump inhibitors are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracycl sulfenamide (see Figure 49–2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H⁺,K⁺-ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24– 48-h) suppression of acid secretion, despite the much shorter plasma t½, of about 0.5–3 h of the parent compounds. Because they block the final step in acid production, the PPIs effectively suppress stimulated acid production, regardless of the physiological stimulus, as well as basal acid production.

The amount of H⁺,K⁺-ATPase increases after fasting; therefore, PPIs should be given before the first meal of the day. In most individuals, once-daily dosing is sufficient to achieve an effective level of acid inhibition, and a second dose, which is occasionally necessary, can be administered before an evening mea. Rebound acid hypersecretion occurs following prolonged treatment with PPIs, and clinical studies suggest that rebound after ceasing treatment can provoke symptoms such as dyspepsia.

To prevent degradation of PPIs by acid in the gastric lumen and improve oral bioavailability, oral dosage forms are supplied in different formulations:

- Enteric-coated pellets within gelatin capsules (omeprazole, dexlansoprazole, esomeprazole, lansoprazole, rabeprazole)  
- Delayed-release tablets (omeprazole formulations)  
- Delayed-release capsules (dexlansoprazole, esomeprazole formulations)  
- Delayed-release oral suspension packets (esomeprazole, pantoprazole, pantoprazole)  
- Enteric-coated microgranules in orally disintegrating tablets (lanosoprazole)  
- Enteric-coated tablets (pantoprazole, rabeprazole, and omeprazole)  
- Powdered omeprazole combined with sodium bicarbonate (capsules and oral suspension)

The delayed-release and enteric-coated tablets dissolve only at alkaline pH, whereas admixture of omeprazole with sodium bicarbonate simply neutralizes stomach acid; both strategies substantially improve the oral bioavailability of these acid-labile drugs. Patients for whom the oral route of administration is not available can be treated parenterally with esomeprazole sodium or pantoprazole.

ADME

Because an acidic pH in the parietal cell acid canaliculi is required for drug activation and food stimulates acid production, these drugs ideally should be given about 30 min before meals. Concurrent administration of food may reduce somewhat the rate of absorption of PPIs, but this effect is not thought to be clinically significant. Once in the small bowel, PPIs are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Asians are more likely...
Figure 49–1  Pharmacologist’s view of gastric secretion and its regulation: the basis for therapy of acid-peptic disorders. Shown are the interactions among neural input and a variety of enteroendocrine cells: an ECL cell that secretes histamine, a ganglion cell of the ENS, a G cell that secretes gastrin, a parietal cell that secretes acid, and a superficial epithelial cell that secretes mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (−). 1 and 3 indicate possible inputs from postganglionic cholinergic fibers; 2 shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include ACh and its muscarinic (M) and nicotinic (N) receptors; GRP and its receptor, the BB bombesin receptor; gastrin and its receptor, the CCK2; HIST and the H2 receptor; and PGE2 and the EP3 receptor. A red line with a T bar indicates sites of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in red are drugs used to treat acid-peptic disorders. NSAIDs can induce ulcers via inhibition of cyclooxygenase. Not shown is a physiological pathway that reduces acid secretion: a D cell that secretes SST, which inhibits G-cell release of gastrin.

Figure 49–2  Activation of a PPI from its prodrug form. Omeprazole is converted to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulphydryl groups in the proton pump, thereby irreversibly inhibiting its activity. Lansoprazole, rabeprazole, and pantoprazole undergo analogous conversions.
Therapeutic Uses and Adverse Effects

Prescription PPIs are primarily used to promote healing of gastric and duodenal ulcers and to treat GERD, including erosive esophagitis, which is either complicated or unresponsive to treatment with H₂ receptor antagonists. They are also used in conjunction with antibiotics for the eradication of Helicobacter pylori. PPIs are also the mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. Lansoprazole, pantoprazole, and esomeprazole are approved for treatment and prevention of recurrence of NSAID-associated gastric ulcers in patients who continue NSAID use. It is not clear if PPIs affect the susceptibility to NSAID-induced damage and bleeding in the small and large intestine. All PPIs are approved for reducing the risk of duodenal ulcer recurrence associated with H. pylori infections. Over-the-counter omeprazole, esomeprazole, and lansoprazole are approved for the self-treatment of acid reflux. Therapeutic applications of the PPIs are discussed further in the section Therapeutic Strategies for Specific Acid-Peptic Disorders.

The PPIs generally cause remarkably few adverse effects and have an excellent safety record (Chen et al., 2012; Reimer, 2013). The most common side effects are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, interstitial nephritis, and skin rashes also have been reported. PPIs are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. PPIs have been observed to interact with warfarin (esomeprazole, lansoprazole, omeprazole, and rabeprazole); diazepam (esomeprazole and omeprazole); and cyclosporine (omeprazole and rabeprazole). Among the PPIs, only omeprazole inhibits CYP2C19 (thereby decreasing the clearance of disulfiram, phenytoin, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of imipramine, several antipsychotic drugs, tacrine, and theophylline). There is some evidence that PPIs can inhibit conversion of clopidogrel (at the level of CYP2C19) to the active anticoagulating form, but this is controversial (Huang et al., 2012). Pantoprazole is less likely to result in this interaction; concurrent use of clopidogrel and PPIs (mainly pantoprazole) significantly reduces GI bleeding without increasing adverse cardiac events (see Chapter 32). Another drug interaction is between methotrexate and PPI therapy because PPIs can competitively inhibit methotrexate elimination and thereby increase methotrexate levels. Chronic treatment with omeprazole decreases the absorption of vitamin B₁₂, but the clinical relevance of this effect is not clear. Loss of gastric acidity also may affect the bioavailability of such drugs as ketoconazole, ampicillin esters, and iron salts. Chronic use of PPIs has been reported to be associated with an increased risk of bone fracture and with increased susceptibility to certain infections (e.g., hospital-acquired pneumonia, community-acquired Clostridium difficile, spontaneous bacterial peritonitis in patients with ascites). Hypergastrinemia is more frequent and more severe with PPIs than with H₂ receptor antagonists and associated with this is ECL hyperplasia, fundic gland polyposis, and atrophic gastritis. This hypergastrinemia may predispose to rebound hypersecretion of gastric acid on discontinuation of therapy and also may promote the growth of GI tumors, although the risk appears very low (Song et al., 2014). Recently, there have been associations made between long-term PPI use and increased risk of chronic kidney disease and dementia. These studies are not yet supported by well-controlled prospective trials and the evidence for these significant adverse effects remains very limited (Freedberg et al., 2017).

H₂ Receptor Antagonists

The arrival of selective histamine H₂ receptor antagonists was a landmark in the treatment of acid-peptic disease. Before the availability of the H₂ receptor antagonists, the standard of care was simply acid neutralization in the stomach lumen, generally with inadequate results. The long history of safety and efficacy with the H₂ receptor antagonists led to their availability without a prescription. Increasingly, however, PPIs are replacing the H₂ receptor antagonists in clinical practice.

Mechanism of Action and Pharmacology

The H₂ receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂ receptors on the basolateral membrane of parietal cells (Black, 1993). Four different H₂ receptor antagonists, which differ mainly in their pharmacokinetics and propensity to cause drug interactions, are available in the U.S.: cimetidine, ranitidine, famotidine, and nizatidine. These drugs are less potent than PPIs but still suppress 24-hour gastric acid secretion by about 70%. Suppression of basal and nocturnal acid secretion is about 70%; because suppression of nocturnal acid secretion is important in the healing of duodenal ulcers, evening dosing of an H₂ receptor antagonist is adequate therapy in most cases. There is little evidence for the use of H₂ receptor antagonists for the treatment of bleeding ulcers, and they are no longer recommended for this purpose. All four H₂ receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available for use in critically ill patients (Table 49–1).

ADME

The H₂ receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations within 1–3 h. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4–5 h (cimetidine), 6–9 h (ranitidine), and 6–8 h (famotidine).
(ranitidine), or 10–12 h (famotidine). The $t_{1/2}$ values of these agents after oral administration in adults range from 1 to 3.5 h; cimetidine clearance is faster in children, reducing its $t_{1/2}$ by about 30%. Only a small fraction of these drugs is protein bound. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce drug doses in patients with decreased creatinine clearance. Neither hemodilution nor peritoneal dialysis clears significant amounts of these drugs. Hepatic metabolism accounts for a small fraction of clearance (from <10% to about 35%), but liver disease per se is generally not an indication for dose adjustment.

**Therapeutic Uses and Adverse Effects**

The major therapeutic indications for H$_2$ receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers. For more information about the therapeutic applications of H$_2$ receptor antagonists, see Therapeutic Strategies for Specific Acid-Pepcid Disorders.

The H$_2$ receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects (Sabesin, 1993). Side effects are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less-common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Several reports have associated H$_2$ receptor antagonists with various blood disorders, including thrombocytopenia. H$_2$ receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these agents, caution is warranted when they are used in pregnancy.

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H$_2$ receptor antagonists (see Antacids section). Drug interactions with H$_2$ receptor antagonists may occur with cimetidine, and its use has decreased markedly. Cimetidine inhibits CYPs (e.g., CYP1A2, CYP2C9, and CYP2D6) and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. Ranitidine also interacts with hepatic CYPs, but with an affinity of only 10% of that of cimetidine. Famotidine and nizatidine are even safer in this regard. Slight increases in blood alcohol concentration may result from concomitant use of H$_2$ receptor antagonists and alcohol.

**Tolerance and Rebound With Acid-Suppressing Medications**

Tolerance to the acid-suppressing effects of H$_2$ receptor antagonists may develop within 3 days of starting treatment and may be resistant to increased doses of the medications (Sandevik et al., 1997). Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells.

**Agents That Enhance Mucosal Defense**

**Misoprostol**

Misoprostol (15-deoxy-16-hydroxy-16-methyl-PGE$_1$) is a synthetic analogue of PGE, that is FDA approved to prevent NSAID-induced mucosal injury.

**Mechanism of Action and Pharmacology**

Prostaglandin E$_2$ and prostacyclin (PGI$_2$) are the major PGs synthesized by the gastric mucosa. Contrary to their cyclic AMP–elevating effects on many cells via E$_1$ and E$_2$ receptors, these prostanoids bind to the E$_2$ receptor on parietal cells and stimulate the G pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE$_2$ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Acid suppression appears to be the most important effect clinically (Wolfle and Sachs, 2000).

Because NSAIDs diminish PG formation by inhibiting cyclooxygenase, synthetic PG analogues offer a logical approach to counteract NSAID-induced damage.

**ADME**

Misoprostol is rapidly absorbed after oral administration and is rapidly and extensively deesterified to form misoprostol acid, the principal and active metabolite of the drug. A single dose inhibits acid production within 30 min; the therapeutic effect peaks at 60–90 min and lasts for up to 3 h. Food and antacids decrease the rate of misoprostol absorption. The free acid is excreted mainly in the urine, with an elimination $t_{1/2}$ of 20–40 min.

**Therapeutic Uses and Adverse Effects**

Misoprostol is rarely used because of its side effects (Rostom et al., 2009). The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100–200 μg significantly inhibit basal acid secretion (up to 85%–95% inhibition) or food-stimulated acid secretion (up to 75%–85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 μg four times a day. Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take misoprostol. Apparently dose related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe cases may necessitate drug discontinuation. Misoprostol can cause clinical exacerbations of inflammatory bowel disease (see Chapter 51). Misoprostol is contraindicated for reducing the risk of NSAID-induced ulcer in women of childbearing potential unless the patient is at high risk of complications from gastric ulcers associated with use of the NSAID. It is also completely contraindicated during pregnancy because it can increase uterine contractility.

**Sucralfate**

**Mechanism of Action and Pharmacology**

In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. Sucralfate consists of the octasulfate of sucrose to which Al(OH)$_3$ has been added. In an acid environment (pH < 4), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 h after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, sucralfate may have other cytoprotective effects, including stimulation of local production of PGs and epidermal growth factor (Szabo, 2014). Sucralfate also binds bile salts; thus, some clinicians use sucralfate to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

**Therapeutic Uses and Adverse Effects**

The use of sucralfate to treat peptic acid disease has diminished in recent years. Nevertheless, because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, sucralfate may offer an advantage over PPIs and H$_2$ receptor antagonists for the prophylaxis of stress ulcers. Sucralfate also has been used in conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastritis. Administered by rectal enema, sucral fate also has been used for radiation proctitis and solitary rectal ulcers. Because it is activated by acid, sucralfate should be taken on an empty stomach 1 h before meals. Use of antacids within 30 min of a dose of sucralfate should be avoided. The dose of sucralfate is 1 g four times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy). For children, it is given 40–80 mg/kg/d in divided doses every 6 h.

The most common side effect of sucralfate is constipation (about 2%). Sucralfate should be avoided in patients with renal failure who are at risk for aluminum overload (Marks, 1991). Likewise, aluminum-containing antacids should not be combined with sucralfate in these patients. Sucralfate forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetidine, ketocanozole, and fluoroquinolone antibiotics. Sucralfate therefore should be
taken at least 2 h after the administration of other drugs. The “sticky” nature of the viscous gel produced by sucralfate in the stomach also may be responsible for the development of bezoars in some patients.

**Antacids**

**Mechanism of Action and Pharmacology**

There are far more effective and persistent agents than antacids, but their price, accessibility, and rapid action make them popular with consumers as OTC medications, and they can be used for the acute treatment of acid reflux ("heartburn") and esophagitis (see discussion that follows). Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. CaCO\textsubscript{3} rapidly and effectively neutralizes gastric H\textsuperscript{+}, but the release of CO\textsubscript{2} from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration. Combinations of Mg\textsuperscript{2+} (rapidly reacting) and Al\textsuperscript{3+} (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. Magaldrate, a hydroxymagnesium aluminate complex, is converted rapidly in gastric acid to Mg(OH)\textsubscript{2} and Al(OH)\textsubscript{3}, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of Mg\textsuperscript{2+} and Al\textsuperscript{3+} theoretically counteract the adverse effects of each other on the bowel (Al\textsuperscript{3+} can relax gastric smooth muscle, producing delayed gastric emptying and constipation; Mg\textsuperscript{2+} exerts the opposite effects), such balance is not always achieved in practice. Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with aspirin, that are marketed for “acid indigestion” are potentially unsafe in patients predisposed to gastroduodenal ulcers and should not be used.

**Therapeutic Uses and Adverse Effects**

Antacids are given orally 1 and 3 h after meals and at bedtime. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30–60 min. In general, antacids should be administered in suspension form because this probably has greater neutralizing capacity than powder or tablet dosage forms. Antacids are cleared from the empty stomach in 30–60 min. In general, the presence of food is sufficient to elevate gastric pH to about 5 for about 1 h and to prolong the neutralizing effects of antacids for about 2–3 h.

Antacids vary in the extent to which they are absorbed and hence in their systemic effects. In general, most antacids can elevate urinary pH by about 1 pH unit. Antacids that contain Al\textsuperscript{3+}, Ca\textsuperscript{2+}, or Mg\textsuperscript{2+} are absorbed less completely than are those that contain NaHCO\textsubscript{3}. With renal insufficiency, absorbed Al\textsuperscript{3+} can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca\textsuperscript{2+} is absorbed, causing transient hypercalcemia. The hypercalcemia from as little as 3–4 g of CaCO\textsubscript{3} per day can be problematic in patients with uremia. In the past, when large doses of NaHCO\textsubscript{3} and CaCO\textsubscript{3} were administered commonly with milk or cream for the management of peptic ulcer, the *milk-alkali syndrome* (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca\textsuperscript{2+} (five to forty 500-mg tablets per day of calcium carbonate) taken with milk.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, allopurinol, and imidazole antifungals, by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al\textsuperscript{3+} and Mg\textsuperscript{2+} antacids also are notable for their propensity to chelate other drugs present in the GI tract and thereby decrease their absorption. Most interactions can be avoided by taking antacids 2 h before or after ingestion of other drugs.

**Other Acid Suppressants and Cytoprotectants**

The M\textsubscript{1} muscarinic receptor antagonists pirenzepine and telzepine (see Chapter 9) can reduce basal acid production by 40%–50%. The ACh receptor on the parietal cell itself is of the M\textsubscript{1} subtype, and these drugs are believed to suppress neural stimulation of acid production via actions on M\textsubscript{1} receptors of intramural ganglia (see Figure 49–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (pirenzepine), they rarely are used today.

Rebamipide is used for ulcer therapy in parts of India and Asia. Its cytoprotective effects are exerted by increasing PG generation in gastric mucosa and by scavenging reactive oxygen species. Ecabat, which appears to increase the formation of PGE, and PGI\textsubscript{2}, also is used for ulcer therapy, mostly in Japan. Carbenoxolone, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Unfortunately, carbenoxolone inhibits the type 1 isozyme of 11β-hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (see Chapter 46). Bismuth compounds (see Chapter 50) are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucus and bicarbonate production, and have significant antibacterial effects.

---

**Therapeutic Strategies for Specific Acid-Peptic Disorders**

**Gastroesophageal Reflux Disease**

Although most cases of acid reflux or gastroesophageal regurgitation follow a relatively benign course, these symptoms, often referred to as nonerosive reflux disease, can still be troubling (Boeckxstaens et al., 2014).

More severe GERD is erosive esophagitis, characterized by endoscopically visible mucosal damage. This can lead to stricture formation and Barrett metaplasia (replacement of squamous by intestinal columnar epithelium), which is associated with a small but significant risk of adenocarcinoma. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis (Alta1 et al., 2012). PPIs clearly are more effective than \(H_2\) receptor antagonists in achieving these goals (see Figure 49–3).

In general, the optimal dose for each patient is determined based on symptom control. Stuctures associated with GERD also respond better to PPIs than to \(H_2\) receptor antagonists. One of the complications of GERD, Barrett esophagus, appears to be more refractory to therapy because neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia.

Regimens for the treatment of GERD with PPIs and histamine \(H_2\) receptor antagonists are listed in Table 49–2. Although some patients with

§Varies by weight.
∥Used when oral PPI cannot be given; short-term use only.

mild GERD symptoms may be managed by nocturnal doses of H₂ receptor antagonists, twice-daily dosing usually is required. Antacids are insufficient and are recommended only for the patient with mild, infrequent episodes of acute acid reflux. In general, prokinetic agents (see Chapter 50) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications. There is reasonable evidence that PPIs, and, to a lesser extent, H₂ receptor antagonists, are safe and effective for the treatment of GERD in children (Tighe et al., 2014).

**Severe Symptoms and Nocturnal Acid Breakthrough**

In patients with severe symptoms or extraintestinal manifestations of GERD, twice-daily dosing with a PPI may be needed. However, it is difficult, if not impossible, to render patients achlorhydric, and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called nocturnal acid breakthrough, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion remains to be established. Patients with continuing symptoms on twice-daily PPIs are often treated by adding an H₂ receptor antagonist at night. Although this can further suppress acid production, the effect is short-lived, probably due to the development of tolerance (Fackler et al., 2002).

**Therapy for Extraintestinal Manifestations of GERD**

Acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other ear, nose, and throat conditions. PPIs (at higher doses) have been used with some success in certain patients with these disorders.

**GERD and Pregnancy**

Acid reflux is estimated to occur in 30%–50% of pregnancies, with an incidence approaching 80% in some populations (Richter, 2003). In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of safety data about use during pregnancy for the most commonly used drugs. In general, most drugs used to treat GERD fall in FDA category B, with the exception of omeprazole (FDA category C; see Appendix I for information on these categories). Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H₂ receptor antagonists can be used, with ranitidine having the most established track record in this setting. PPIs are reserved for women with intractable symptoms or complicated reflux disease. In these situations, omeprazole, lansoprazole, and pantoprazole are considered the safest choices (Ali and Egan, 2007).

**Pediatric GERD**

Reflex disease in infants and children is increasing at an alarming rate (Vandenplas, 2014). Children over 10 years can be diagnosed and treated similarly to adults, but infants and very young children require careful diagnosis to rule out cow’s milk allergy or eosinophilic esophagitis. Many nonpharmacologic approaches can be used to alleviate some of the very troubling symptoms of this condition, which may not be due to acid reflux. If acid reduction is indicated, PPIs are more effective than H₂ receptor antagonists; however, the therapeutic efficacy of PPIs in newborns and infants is low, and there is an increased risk of adverse effects,
including respiratory tract infections and gastroenteritis, which should be carefully considered. It is likely PPIs are overused in the treatment of pediatric GERD.

**Peptic Ulcer Disease**

Peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, PG, NO, and other peptides and growth factors) and injurious factors (acid and pepsin) (Hunt et al., 2015; Wallace, 2008). On average, patients with **duodenal ulcers** produce more acid than do control subjects, particularly at night (basal secretion). Although patients with **gastric ulcers** have normal or even diminished acid production, ulcers rarely, if ever, occur in the complete absence of acid. Presumably, weakened mucosal defense and reduced bicarbonate production contribute to the injury from the relatively lower levels of acid in these patients. **Helicobacter pylori** and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with **H. pylori** infection of the stomach. This infection may lead to impaired production of somatostatin by D-cells and, in time, cause decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production. Table 49–3 summarizes current recommendations for drug therapy of gastro-duodenal ulcers.

The PPIs relieve symptoms of duodenal ulcers and promote healing more rapidly than do H₂ receptor antagonists, although both classes of drugs are effective in this setting (see Figure 49–3). A peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation that **H. pylori** plays a major etiopathogenic role in the majority of peptic ulcers, prevention of relapse is focused on eliminating this organism from the stomach. Intravenous esomeprazole (80 mg IV over 30 min, followed by 8 mg/h continuous infusion for a total of 72 h, then 40 mg orally or another single daily dose oral PPI, for an appropriate duration; off-label use) and pantoprazole (off-label use) are the preferred therapy in patients with acute bleeding ulcers (Laine and Jensen, 2012; Wong and Sung, 2013). The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

**Treatement of Helicobacter pylori infection**

**Helicobacter pylori**, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma (Suèraubm and Michetti, 2002). Because of the critical role of **H. pylori** in the pathogenesis of peptic ulcers, eradicating this infection is standard care in patients with gastric or duodenal ulcers (Malfertheiner et al., 2013). Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of **H. pylori** also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment. **Helicobacter pylori** eradication is also indicated for treatment of chronic atrophic gastritis and presence of intestinal metaplasia/dysplasia (with positive **H. pylori** biopsies).

Five important considerations influence the selection of an eradication regimen (Table 49–4) (Chey and Wong, 2007; Malfertheiner et al., 2012):

- Single-antibiotic regimens are ineffective in eradicating **H. pylori** infection and lead to microbial resistance. Combination therapy with two or three antibiotics (plus acid-suppressive therapy) is associated with the highest rate of **H. pylori** eradication.
- A PPI significantly enhances the effectiveness of **H. pylori** antibiotic regimens containing amoxicillin and clarithromycin (see Figure 49–3).
- A regimen of 10–14 days of treatment appears to be better than shorter regimens.
- Poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens and to the inconvenience of three- or four-drug regimens administered several times per day. Packaging that combines the daily doses into one convenient unit is available and may improve patient compliance.

*There is little evidence for the use of H₂ receptor antagonists for the treatment of bleeding ulcers.

°Deslansoprazole is not labeled for the treatment of active ulcers.

°Off-label use.

°Only misoprostol 800 μg/d has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction. (Rostom A, Moayyedi P, Hunt R. Canadian Association of Gastroenterology Consensus Group. Canadian consensus guidelines on long-term nonsteroidal anti-inflammatory drug therapy and the need for gastroprotection: benefits versus risks. *Aliment Pharmacol Ther*, 2009, 29:481–496.)
Now that intravenous preparations of PPIs are available, they are appropriately indicated in the context of a profound illness or trauma requiring intensive care (Bardou et al., 2015). The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H₂ receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of PPIs are available, they are appropriate to consider. However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu. In this setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia.

*Off-label use.*

Data from Chey and Wong, 2007.

### NSAID-Related Ulcers

Chronic NSAID users have a 2%–4% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. Healing of ulcers despite continued NSAID use is possible with the use of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (e.g., ≥ 8 weeks). PPIs are superior to H₂ receptor antagonists and misoprostol in promoting the healing of active ulcers and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration (Lanas and Hunt, 2006; Rostom et al., 2009). The FDA has approved fixed-dose combinations of NSAIDs with a PPI or H₂ antagonist; these combinations are intended to lower the risk of ulcers in patients who regularly use NSAIDs for arthritic pain.

### Stress-Related Ulcers

Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care (Bardou et al., 2015). The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H₂ receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of PPIs are available, they are appropriate to consider. However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu. In this setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia.

### Zollinger-Ellison Syndrome

Patients with Zollinger-Ellison syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I (Krampitz and Norton, 2013). This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchylorhydria. PPIs are the drugs of choice, usually given at about twice the routine dosage for peptic ulcers (omeprazole 60 mg daily, esomeprazole 80 mg daily, lansoprazole 60 mg daily, rabeprazole 60 mg daily, or pantoprazole 120 mg daily); some patients need two to three times these doses to control acid secretion. However, once control of acid secretion has been achieved, dose reduction is usually possible. PPIs are well tolerated and safe even at very high doses. If PPIs are unable to control gastric acid secretion, the long-acting somatostatin analogue octreotide (off-label indication) can be given to inhibit secretion of gastrin. This is not a first-line agent due to unpredictable response rates and the side effects of the treatment.

### Functional Dyspepsia

The term functional dyspepsia refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration (Tack and Talley, 2013). Functional dyspepsia can be subdivided into postprandial distress syndrome and epigastric pain syndrome, based on the presence of symptoms related to meals. It is defined as the presence of one or more of the following: postprandial fullness, early satiation, epigastric pain or burning, and no evidence of structural disease. It may be associated with gastritis (with or without H. pylori) or with NSAID use, but the pathogenesis of this syndrome remains controversial.

The PPIs appear to be moderately effective in the treatment of patients with functional dyspepsia (Vanheel and Tack, 2014). In general, twice-daily PPIs are no better than once-daily PPIs. The dosing is as for GERD (Table 49–2). H₂ receptor antagonists are only marginally effective for the treatment of functional dyspepsia. Because central mechanisms may contribute to functional dyspepsia either through visceral hypersensitivity or other mechanisms, tricyclic antidepressants such as amitriptyline or desipramine (10 to 25 mg at night) (see Chapter 15) can be considered in patients with functional dyspepsia whose symptoms persist despite PPI therapy for 8 weeks. Prokinetic agents such as metoclopramide (see Chapter 50) are not considered for functional dyspepsia because of their side-effect profile. The novel gastroprokinetic agent acotiamide is being investigated for use in postprandial distress syndrome, and SHT₂-serotonin receptor agonists that relax the fundus (see Chapter 13) are being tested in patients with postprandial distress syndrome with early satiation. Antacids are not generally helpful for the treatment of functional dyspepsia.

### Functional Esophageal Disorders

Functional esophageal disorders are disorders that cause esophageal symptoms and that are diagnosed on the basis of negative results on standard esophageal tests, thereby excluding structural disorders, motility disorders like achalasia, and GERD (Amarasinghe and Sifrim, 2014). There are four of these fairly common disorders: (1) functional heartburn, (2) functional chest pain, (3) functional dysphagia, and (4) globus. PPI therapy (off-label use) as outlined previously is routinely used for the initial treatment of functional heartburn, functional chest pain, and globus. As in functional dyspepsia, central mechanisms contribute to these disorders and similar approaches follow for the treatment of functional heartburn and functional chest pain if PPI therapy is ineffective, including the use of tricyclic antidepressants or selective serotonin reuptake inhibitors. For the treatment of globus, gabapentin or pregabaline is used.

Gastrointestinal Motility

The GI tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle and epithelium, the enteric nervous system (ENS), the autonomic nervous system (ANS), and local and circulating hormones. Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 50–1) (Furness, 2006; Furness, 2012; Grundy et al., 2006).

The ENS is an extensive collection of nerves and glial cells that constitutes the third division of the ANS. It is the only part of the ANS truly capable of autonomous function if separated from the CNS. The ENS lies within the wall of the GI tract and is organized into two connected networks of neurons, nerve fibers, and glial cells: the myenteric (Auerbach) plexus, found between the circular and longitudinal muscle layers, and the submucosal (Meissner) plexus, located in the submucosa (Furness, 2012; Sharkey, 2015). The former is largely responsible for motor control, whereas the latter regulates secretion, fluid transport, and blood flow.

To prevent the unwanted translocation of toxins, antigen commensal bacteria, and other potentially pathogenic components of the luminal contents, an elaborate “intestinal barrier” has developed. This consists of a physical barrier, an immune barrier, and a secretory barrier, which includes the secretion of antimicrobial peptides, mucus, and fluid. The secretory and immune components of the intestinal barrier are regulated by ENS and ANS neural mechanisms that integrate the control of these components of barrier function with digestive processes in the gut (Mayer et al., 2014; Sharkey and Savidge, 2014).

Generation and Regulation of GI Motor Activity

The ENS is responsible for the largely autonomous nature of most GI activity. This activity is organized into relatively distinct programs that respond to input from the local environment of the gut, as well as the ANS-CNS. Each program consists of a series of complex, but coordinated, patterns of secretion and movement that show regional and temporal variation (Deloose et al., 2012). The fasting program of motor activity in the gut is called the MMC (migrating myoelectric complex when referring to electrical activity and migrating motor complex when referring to the accompanying contractions) and consists of a series of four phasic activities: I, quiescence; II, increasing frequencies of action potentials and smooth muscle contractions; III, peak contractile activity; and IV, declining activity toward a renewal of phase I. Phase II of the MMC is associated with the release of the peptide hormone motilin. Motilin agonists stimulate motility in the proximal gut. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6–10 min before proceeding caudally (toward the anus). One MMC cycle (i.e., all four phases) takes about 80–110 min. The MMC occurs in the fasting state, helping to sweep debris caudal in the gut and limiting the overgrowth of commensal luminal bacteria. The MMC is interrupted by the fed program in intermittently feeding animals such as humans. The fed program consists of high-frequency (12–15/min) contractions that either are propagated for short segments (propulsive) or are irregular and not propagated (mixing).

Peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, whereas the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudal. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems), which are of two broad types, excitatory and inhibitory. The primary neurotransmitter of the excitatory motor neurons is ACh. The principal neurotransmitter in the inhibitory motor neurons is NO, although important contributions may also be made by ATP, VIP, and PACAP. Enterochromaffin cells, the major population of enterococrine cells, scattered throughout the epithelium of the intestine, release serotonin (SHT) to initiate many gut reflexes by acting locally on enteroendocrine cells (Gershon and Tack, 2007). Excessive release of SHT in the gut...
Excitation Contraction Coupling in GI Smooth Muscle

Control of tension in GI smooth muscle is dependent on the intracellular Ca²⁺ concentration (Sanders et al., 2012). There are basically two types of excitation-contraction coupling in these cells. **Ionotropic receptors** can mediate changes in membrane potential, which in turn activate voltage-gated Ca²⁺ channels to trigger an influx of Ca²⁺ (electromechanical coupling); **metabotropic receptors** activate various signal transduction pathways to release Ca²⁺ from intracellular stores (pharmacomechanical coupling). Inhibitory receptors act via PKA and PKG and lead to hyperpolarization, decreased cytosolic [Ca²⁺], and reduced interaction of actin and myosin. As an example, NO may induce relaxation via activation of the guanylyl cyclase–cyclic GMP pathway and cause the opening of several types of K⁺ channels.

**Functional and Motility Disorders of the Bowel**

Gastrointestinal motility disorders are a heterogeneous group of conditions (Drossman, 2006; Faure et al., 2012). Common motility disorders include achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), GERD (chronic reflux of gastric contents into the esophagus due to an increased frequency of transient lower esophageal sphincter relaxations, ineffective esophageal peristalsis, or gastric dysmotility); intestinal pseudoobstruction (myopathic and neuropathic forms of intestinal dysmotility); constipation; Hirschsprung disease; anorectal dysfunctions (Drossman, 2006; Faure et al., 2012). Common motility disorders involve most cases.

Prokinetic agents and other stimulants of GI motility

Prokinetic agents are medications that enhance coordinated GI motility and transit of material in the GI tract (Acosta and Camilleri, 2015; Altan et al., 2012; Corsetti and Tack, 2014; Tack and Zaninotto, 2015). These agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. By contrast, activation of muscarinic receptors with the older cholinomimetic agents (see Chapter 9) or acetylcholinesterase inhibitors (see Chapter 10) enhances contractions in a relatively uncoordinated fashion that produces little or no net propulsive motor activity.

Dopamine Receptor Antagonists

Dopamine is present in significant amounts in the GI tract and has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which result from suppression of ACh release from myenteric motor neurons, are mediated by D₁ dopaminergic receptors. Dopamine receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of dopamine receptors in the CTZ of the brainstem. Examples are metoclopramide and domperidone (Acosta and Camilleri, 2015; Reddymasu et al., 2007).
Metoclopramide

Mechanism of Action and Pharmacology. Metoclopramide and other substituted benzamides are derivatives of para-aminobenzoic acid and are structurally related to procainamide. The mechanisms of action of metoclopramide are complex and involve 5HT2 receptor agonism, vagal and central 5HT3 antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to dopamine receptor antagonism. Administration of metoclopramide results in coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. Metoclopramide has no clinically significant effects on large-bowel motility (Acosta and Camilleri, 2015).

ADME. Metoclopramide is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a $t_{1/2}$ of 4–6 h. Peak concentrations occur within 1 h after a single oral dose; the duration of action is 1–2 h.

Therapeutic Uses and Adverse Effects. Metoclopramide is indicated in patients with gastroparesis, in whom the drug may cause moderate improvements of gastric emptying. Metoclopramide injection is used as an adjunctive measure in medical or diagnostic procedures such as upper endoscopy or contrast radiography of the GI tract (single IV dose of 10 mg). Its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes. Metoclopramide is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous or intramuscular administration. The initial regimen is 10 mg orally, 30 min before each meal and at bedtime. The onset of action is within 30–60 min. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10–15 min) or intravenously (onset of action 1–3 min). For prevention of chemotherapy-induced emesis, metoclopramide can be given as an infusion of 1–2 mg/kg administered over at least 15 min, beginning 30 min before the chemotherapy is begun and repeated as needed every 2 h for two doses, then every 3 h for three doses. Because of adverse effects related to drug exposure, the recommended duration of use is less than 12 weeks. Metoclopramide has a very limited use for the treatment of GERD in children because of significant safety concerns (see discussion that follows) and limited efficacy.

The major side effects of metoclopramide include extrapyramidal effects. Dystonias, usually occurring acutely after intravenous administration, and Parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and reverse on discontinuation of metoclopramide. Tardive dyskinesia also can occur with chronic treatment and may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. Metoclopramide also can cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin release (seen infrequently in clinical practice). Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving metoclopramide.

Domperidone

Mechanism of Action and Pharmacology. In contrast to metoclopramide, domperidone predominantly antagonizes the D2 receptor without major involvement of other receptors, but otherwise its mechanism of action is similar (Reddymasu et al., 2007).

ADME. Domperidone is rapidly absorbed, yielding peak concentrations in 30 min. The drug undergoes metabolism via hepatic CYP3A4, N-dealkylation, and hydroxylation; it has a $t_{1/2}$ of 7 h. It is excreted in the feces (–two-thirds) and urine (–one-third).

**GI MOTILITY AND WATER FLUX, EMESIS, BILIARY AND PANCREATIC DISEASE**

---

**Serotonin Receptor Agonists**

Serotonin (5HT) plays an important role in the normal motor and secretory function of the gut (see Chapter 13) (Gershon and Tack, 2007). Indeed, more than 90% of the total 5HT in the body exists in the GI tract. The enterochromaffin cell produces most of this 5HT and rapidly releases it in response to chemical and mechanical stimulation (e.g., food boluses; chemotherapeutic agents such as cisplatin; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5HT acts as a mediator of various neurotransmitter actions that facilitate peristalsis, including the release of other neurotransmitters. Thus, 5HT stimulates the release of other neurotransmitters in the myenteric plexus (via 5HT1A, 5HT3, and 5HT4 receptors), as well as extrinsic vagal and spinal sensory neurons (via 5HT1p receptors). In addition, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes, resulting in epithelial secretion.

The 5HT receptors occur on other neurons in the ENS, where they can be either stimulatory (5HT1A and 5HT3) or inhibitory (5HT1D). In addition, serotonin stimulates the release of other neurotransmitters. Thus, 5HT stimulation of the gastric fundus results in release of NO and reduction in smooth muscle tone. 5HT2 stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5HT1A and 5HT3 receptors facilitate interneuronal signaling. Developmentally, 5HT acts as a neurotrophic factor for enteric neurons via the 5HT4 receptor. Reuptake of serotonin by enteric neurons and epithelium is mediated by the same transporter (SERT) as 5HT reuptake by serotonergic neurons in the CNS. This reuptake also is blocked by SSRIs (see Figure 15–1), which explains the common side effect of diarrhea that accompanies the use of these agents (Gershon, 2013).

Modulation of the multiple, complex, and sometimes-opposing effects of 5HT on gut motor function has become a major target for drug development. The availability of serotoninergic prokinetic drugs has increased in recent years, although many have been withdrawn due to a variety of adverse effects. The availability of serotoninergic prokinetic drugs has increased in recent years, with a variety of adverse effects. The availability of serotoninergic prokinetic drugs has increased in recent years, with a variety of adverse effects.

**Cisapride**

**Mechanism of Action and Pharmacology.** Cisapride is a 5HT3 agonist that stimulates adenyl cyclase activity in neurons. It also has weak 5HT4 antagonistic properties and may directly stimulate smooth muscle. Cisapride was a commonly used prokinetic agent; however, it no longer is generally available in the U.S. because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. These arrhythmias result from a prolonged QT interval through an interaction with pore-forming subunits of the HERG K+ channel (see Chapter 30).

**ADME.** Cisapride is metabolized in the liver by CYP3A4 (see Chapter 6). It has an onset of action of 30–60 min and a t1/2 of 6–12 h.

**Therapeutic Uses and Adverse Effects.** Cisapride is available only through an investigational, limited-access program for patients with GERD, gastroparesis, intestinal pseudoobstruction, refractory severe chronic constipation, and neonatal enteral feeding intolerance who have failed all standard therapeutic modalities and who have undergone a thorough diagnostic evaluation, including an ECG. It has modest prokinetic activity in doses of 5–10 mg four times a day before meals. Cisapride is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities, or concomitant medications known to prolong the QT interval.

**Prucalopride**

**Mechanism of Action and Pharmacology.** Prucalopride is a specific 5HT4 receptor agonist (Figure 50–2) that facilitates cholinergic neurotransmission. It acts throughout the length of the intestine, increasing oral-cecal transit and colonic transit without affecting gastric emptying in healthy volunteers.

**ADME.** Prucalopride has a time to peak action of 2–3 h and a t1/2 of 24 h. It is primarily excreted in the urine as the unchanged drug.

**Therapeutic Uses and Adverse Effects.** Given in doses of 1–4 mg orally, once daily, the drug improved bowel habits; significantly increased the number of spontaneous, complete bowel movements; reduced the severity of symptoms; and improved quality of life in patients with severe chronic constipation. Prucalopride is approved or use in women with chronic constipation in whom laxatives fail to provide adequate relief. Nausea, diarrhea, abdominal pain, and headaches are common adverse effects. Cardiovascular risks do not seem to be elevated, but patients should be monitored (Diederen et al., 2015).

**Motilin and Macrolide Antibiotics**

**Mechanism of Action and Pharmacology.** Motilin, a 22–amino acid peptide hormone secreted by enteroendocrine M cells and by some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the MMC and appear to be responsible for the amplification, if not the actual induction, of phase III activity. In addition, motilin receptors are GPCRs found on smooth muscle cells and enteric neurons.

The effects of motilin can be mimicked by erythromycin, a property shared to varying extents by other macrolide antibiotics (e.g., azithromycin, clarithromycin, etc.; see Chapter 59). In addition to its motilin-like effects, which are most pronounced at higher doses (250–500 mg), erythromycin at lower doses (e.g., 40–80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation. Erythromycin has multiple effects on upper GI motility, increasing lower esophageal pressure.
and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

**ADME**

*Erythromycin* is metabolized by demethylation in the liver by CYP3A4. The time to peak action is about 0.5–2.5 h (ethylsuccinate), and it has a $t_{1/2}$ of 2 h. It is primarily excreted in the feces. Rapid development of tolerance (~28 days) to *erythromycin*, possibly by downregulation of the motilin receptor, and antibiotic effects (undesirable in this context) limit the use of this drug as a prokinetic agent. A standard dose of *erythromycin* for gastric stimulation is 1.5–3 mg/kg intravenous infusion every 6 h in a hospital setting or 125 mg orally every 12 h (Acosta and Camilleri, 2015). For small-bowel stimulation, a smaller dose (e.g., 3 mg/kg IV every 8 h) may be more useful; higher doses may actually retard the motility. Tachyphylaxis to *erythromycin* and potential side effects limit its use in the management of gastroparesis. Concerns about GI toxicity, ototoxicity, pseudomembranous colitis, and the induction of resistant strains of bacteria, QT prolongation, and sudden death, particularly when used in patients taking medications that inhibit CYP3A4, limit the use of *erythromycin* to acute situations or in circumstances where patients are resistant to other medications.

Other macrolides (e.g., *azithromycin* and *clarithromycin*) accelerate gastric emptying, but because there are no clinical trials compared to other medications or placebo indicating any benefit, their additional cost, potential for risk, and antibiotic resistance would preclude consideration for their use in motility disorders.

**Miscellaneous Agents for Stimulating Motility**

The hormone CCK is released from the intestine in response to meals and delays gastric emptying, causes contraction of the gallbladder, stimulates pancreatic enzyme secretion, increases intestinal motility, and promotes satiety. The C-terminal octapeptide of CCK, *sincalide*, is useful for stimulating the gallbladder or pancreas and for accelerating barium transit through the small bowel for diagnostic testing of these organs. It is given by intravenous injection or infusion and has an onset of action of 5–15 min. Currently, there are a number of agents under evaluation that stimulate motility whose mechanisms of action are based on well-established neurohumoral mechanisms (Camilleri, 2014). These include a novel *motilin receptor agonist* (camicinal), a *ghrelin receptor agonist* (relamorelin), and novel 5HT4 agonists (*velusetrag* and *naronapride*).

**Agents That Suppress Motility**

Smooth muscle relaxants such as organic nitrates, type 5 phosphodiesterase inhibitors, and Ca2+ channel antagonists produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in severe difficulty in swallowing (Pandolfino and Gawron, 2015). Preparations of botulinum toxin (onabotulinumtoxinA), injected directly into the lower esophageal sphincter via an endoscope, in doses of 80–100 units, inhibit ACh release from nerve endings and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance (Zhao and Pasricha, 2003). Other GI conditions in which botulinum toxin A has been used include gastroparesis, sphincter of Oddi dysfunction, and anal fissures, although currently there are no strong trial data to support its efficacy.

**Laxatives, Cathartics, and Therapy for Constipation**

**Overview of GI Water and Electrolyte Flux**

Water normally accounts for 70%–85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion of fluids and luminally directed secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper expulsion of waste material via the process of defecation.

Normally, about 8–9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 50–3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only about 1–1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving about 100 mL of fecal water daily. Under normal circumstances, these quantities are within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4–5 L). Neurohumoral mechanisms, pathogens, and drugs can alter secretion and absorption of fluid by the intestinal epithelium (Figure 50–4). Altered motility also contributes in a general way to this process. With decreased motility and excess fluid removal, feces can become inpsissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea occurs.

![Figure 50–3](image-url)  
**Figure 50–3** Typical volume and composition of fluid that traverses the small and large intestines daily. Of the 9 L of fluid typically presented to the small intestine each day, 2 L are from the diet and 7 L are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4–5 L per day.
CHAPTER 50

GI MOTILITY AND WATER FLUX, EMESIS, BILIARY AND PANCREATIC DISEASE

Mechanism of action of drugs that alter intestinal epithelial secretion and absorption. A. Agents affecting intestinal epithelial secretion. Secretion is driven in secretory enterocytes by the Na⁺ gradient established by the Na⁺,K⁺-ATPase. This Na⁺ gradient drives the symporter NKCC1 (SLC12A2), which allows for the accumulation of Cl⁻ in the cell. Regulation of chloride channels in the apical (luminal) membrane drives Cl⁻ secretion. Vectorial movement of chloride drives the secretion of water through the paracellular route and through AQP water channels. Chloride secretion is rapidly regulated through phosphorylation of CFTR by the cyclic nucleotide-dependent protein kinases, PKA and PKG. Thus, drugs that stimulate adenylyl cyclase (i.e., misoprostil, acting through prostanoid EP₂ or EP₄ receptors) or GC (linaclootide) will stimulate Cl⁻ and water secretion. Several bacterial toxins cause water efflux and diarrhea by these mechanisms: cholera toxin (CT) and heat-labile Escherichia coli toxin (LT) stimulate cyclic AMP synthesis in the enterocyte by ADP-ribosylating Gαs, blocking its GTPase activity and leading to constitutive activation of adenylyl cyclase; the heat-stable enterotoxins (e.g., STα) stimulate the membrane-bound form of guanylyl cyclase. Drugs that inhibit adenylyl cyclase (e.g., octreotide, acting at SST2 receptors) inhibit secretion. Calcium-dependent chloride channels (TMEM 16A, ClC2) are regulated by increases in cytosolic Ca²⁺, such as that induced by activation of muscarinic M₃ receptors that atropine blocks. Increases in cytosolic cyclic AMP and Ca²⁺ also regulate cyclic AMP-dependent and Ca²⁺-dependent K⁺ channels; this regulation is essential in maintaining the Na⁺ gradient necessary to facilitate secretion. Apical chloride channels (CFTR, TMEM 16A) can also be inhibited by drugs such as lubiprostone and crofelemer. Drugs such as budesonide inhibit NKCC1 function and thereby reduce secretion. B. Agents affecting intestinal epithelial absorption. Absorption is also driven by Na⁺,K⁺-ATPase in absorptive enterocytes, which creates the Na⁺ gradient that facilitates Na⁺ absorption through ENaC or through coupled transporters such as the Na⁺-glucose cotransporter SGLT1 (SLC5A1) and members of the NHE family. ENaC is blocked by amiloride and similar compounds. NHE and the bicarbonate Cl⁻ exchanger, DRA, depend on the action of carbonic anhydrase (CA), which generates H⁺ and HCO₃⁻ from water and CO₂ in the cytosol. Water enters the cell through apical AQPs. As in secretion, regulation of K⁺ channels by cyclic AMP and Ca²⁺ is essential. Thus, drugs that act on α₂ adrenergic receptors (e.g., clonidine) will reduce adenylyl cyclase activity and lower enterocyte cyclic AMP levels, thereby reducing absorption.

Figure 50–4
**Constipation: General Principles of Pathophysiology and Treatment**

Patients use the term *constipation* not only for decreased frequency, but also for difficulty in initiation or passage of firm or small-volume feces or a feeling of incomplete evacuation.

Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation have normal colonic transit. These patients either have IBS or define constipation in terms other than stool frequency. In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility or, less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the rectoanal region.

Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions (Dinning et al., 2009). Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is usually based on nonspecific principles.

Constipation generally may be corrected by adherence to a fiber-rich (20–35 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs (Emmanuel et al., 2009; Lacy et al., 2014; Menees et al., 2012). Constipation related to medications can be corrected by use of alternative drugs where possible or adjustment of dosage. If nonpharmacological measures alone are inadequate, they may be supplemented with bulk-forming agents or osmotic laxatives.

When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period of time to avoid abuse. In addition to perpetuating dependence on drugs, the laxative habit may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported. Laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable. The terms laxatives, cathartics, purgatives, aperients, and evacuants often are used interchangeably. There is a distinction, however, between laxation (the evacuation of formed fecal material from the rectum) and catharsis (the evacuation of unformed, usually watery, fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are actually cathartics that act as laxatives at low doses.

Laxatives relieve constipation and promote evacuation of the bowel via the following:

- enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms;
- decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport; and
- altering motility by inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions.

Laxatives can be classified based on their actions (Table 50–1) or by the pattern of effects produced by the usual clinical dosage (Table 50–2), with some overlap between classifications.

A variety of laxatives, both osmotic agents and stimulants, increases the activity of NO synthase and the biosynthesis of PAF (see Chapter 37) in the gut. PAF is a phospholipid pro-inflammatory mediator that stimulates colonic secretion and GI motility (Izzo et al., 1998). NO also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, magnesium sulfate, and bisacodyl (but not senna).

**Dietary Fiber and Supplements**

Bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is that part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying degrees, depending on its chemical nature and water solubility. Fermentation of fiber has two important effects: (1) It produces short-chain fatty acids that are trophic for colonic epithelium; (2) it increases bacterial mass. Although fermentation of fiber generally decreases stool weight, short-chain fatty acids may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. However, fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 50–3). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit. *Bran*, the residue left when flour is made from cereal grains, contains more than 40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight (a dose of 1–3 g up to three times a day). Fruits and vegetables contain more pectins and hemicelluloses, which are more readily fermentable and produce less effect on stool transit. Psyllium husk, derived from the seed of the plantago herb (*Plantago ovata*; known as ispaghula or isabgol in many parts of the world), is a component of many commercial products for constipation. Psyllium husk contains some overlap between classifications.

<sup>1</sup>Employed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.
of the risks of acute phosphate nephropathy, oral phosphates are not recommended for the treatment of constipation and should be completely avoided in patients at risk (the elderly, patients with known bowel pathology or renal dysfunction, and patients on angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and NSAIDs).

The Mg\(^{2+}\)-containing preparations must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities and in patients on diuretic therapy.

**Nondigestible Sugars and Alcohols.** Lactulose is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other nonabsorbable sugars such as sorbitol and mannitol are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and vincristine, of constipation in the elderly, and of idiopathic chronic constipation. They are available as 70% solutions, which are given in doses of 15–30 mL at night, with increases as needed up to 60 mL/d in divided doses. Effects may not be seen for 24 to 48 h after dosing begins. Abdominal discomfort or distention and flatulence are relatively common but usually subside with continued administration.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in "trapping" of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give sufficient amounts of lactulose (usually 20–30 g three to four times per day) to produce two to three soft stools a day with a pH of 5–5.5.

**Stool-Wetting Agents and Emollients**

**Docusate.** Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool, and permitting easier defecation. These agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. Docusate sodium (diocyl sodium sulfoisuccinate, 100 mg twice per day) and docusate calcium (diocyl calcium sulfoisuccinate, 240 mg per day) are well tolerated but have marginal efficacy in most cases of constipation.

**Mineral Oil.** Mineral oil is a mixture of aliphatic hydrocarbons obtained from petroleum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2–3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include interference with absorption of fat-soluble substances (such as vitamins), elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

**Stimulant (Irritant) Laxatives**

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle and probably induce limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility (Lacy et al., 2014; Paré and Fedorak, 2014). This group includes diphenylmethane derivatives, anthraquinones, and ricinoleic acid.

**Diphenylmethane Derivatives. Bisacodyl.** Bisacodyl is marketed as enteric-coated and regular tablets and as a suppository for rectal administration. The usual oral daily dose of bisacodyl is 10–30 mg for adults and 5–10 mg for children ages 6–12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, so the laxative effects after an oral dose usually are produced in 6–10 h. Suppositories (10 mg) work within 15–60 min. Due to the possibility of developing an atomic nonfunctioning colon, bisacodyl should not be used for more than...
Cascara sagrada is obtained from the bark of the buckthorn tree and contains the glycosides barbaloin and chrysaloin. The synthetic monoanthrones (oral mucosal irritants) are converted to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms.

**Senna.** Senna is obtained from the dried leaves of Cassia angustifolia or Cassia occidentalis and contains the rhein dihydrate and glycosides sennoside A and B. These ingredients may still be sold OTC in the U.S., but legally they cannot be labeled for use as laxatives. This judgment is medically prudent but may provoke a wistfulness among Joyceans, who recall that cascara sagrada, the sacred bark, worked well for Leopold Bloom, in Dublin, on the morning of yesterday quite gone. Hope its not too big to bring on piles again. No, just right. So! Ah! Costive one tabloid of cascara sagrada. Life might be so. (Ulysses, James Joyce, 1922)

**Castor Oil.** A bane of childhood since the time of the ancient Egyptians, castor oil is derived from the bean of the castor plant, Ricinus communis. The castor bean is the source of an extremely toxic protein, ricin, as well as the oil (chiefly of the triglyceride of ricinoleic acid). The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, ricinoleic acid, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 mL of castor oil may produce a laxative effect within 1–3 h; however, the usual dose for a cathartic effect is 15–60 mL for adults. Because of its unpleasant taste and its potential toxic effects on intestinal epithelium and enteric neurons, castor oil is not recommended now.

**Enemas and Suppositories.** Enemas are employed either by themselves or as adjuncts to bowel preparation regimens to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that are either osmotically active or irritant; however, their safety and efficacy have not been studied. Repeated enemas with hypertonic solutions can cause hypotension; repeated enemas with sodium phosphate–containing solution can cause hypocalcemia. **Glycerin.** Glycerin is absorbed when given orally but acts as a hygroscopic agent and lubricant when given rectally. The resultant water reten-

**Prokinetic and Secretory Agents for Constipation**

The term **prokinetic** is reserved for agents that enhance GI transit via interaction with specific receptors involved in the regulation of motility (Acosta and Camilleri, 2015; Altan et al., 2012; Corsetti and Tack, 2014; Tack and Zaninotto, 2015). The potent 5HT4 receptor agonist prucalopride (1–4 mg per day) may be useful for the treatment of chronic constipation. Misoprostol, a synthetic prostaglandin analogue, is primarily used for protection against gastric ulcers resulting from the use of NSAIDs and for the medical termination of pregnancy (see Chapters 37, 44, and 49). Prostaglandins can stimulate colonic contractions, particularly in the descending colon; this may account not only for the diarrhea that limits the usefulness of misoprostol as a gastrointestinal, but also for misoprostol's utility in patients with intractable constipation. Doses of 200 μg daily or every other day can be effective when used with PEG. Misoprostol should not be used in women who could become pregnant because it induces labor. It can also increase menstrual bleeding. Colchicine, a microtubule formation inhibitor used for gout (see Chapter 38), also has been shown to be effective in constipa-
tion (1 mg per day), but its toxicity limits widespread use.

Three recently introduced secretory agents, lubiprostone, linaclotide, and plecanatide, with novel mechanisms of action restricted to the gut lumen, have demonstrated effectiveness in the treatment of chronic constipation in adults.

**Lubiprostone.** **Mechanism of Action and Pharmacology.** Lubiprostone is a protonoid activator of Cl− channels. The drug appears to bind to the EP3 receptor for PGE2, a GPCR that couples to Gs, activating adenyl cyclase and leading to enhanced apical Cl− conductance. The drug promotes the secretion of a chloride-rich fluid, thereby improving stool consistency and promoting increased frequency by reflexly activating motility (Wilson and Schey, 2015).

**Therapeutic Uses and Adverse Effects.** A dose of 8 μg twice daily was found to be effective in constipation-predominant IBS, although higher doses (24 μg twice daily) are given for chronic constipation and opioid-induced constipation (see discussion that follows). The drug is poorly bioavailable, acting only in the lumen of the bowel. Side effects of lubiprostone include nausea (in up to 30% of patients), headache, diarrhea, allergic reactions, and dyspnea.

**Linaclotide.** **Mechanism of Action and Pharmacology.** Another class of secretory agent is linaclotide, a 14-amino acid peptide agonist of the membrane-spanning GC-C. In the intestinal epithelium, GC-C is activated physiologically by guanylin and uroguanylin, pathologically by heat-stable bacterial toxins that cause gaseous and pharmacologically by linaclotide. Activation of GC-C results in increased synthesis of cyclic GMP, resulting in enhanced chloride and bicarbonate secretion into the intestinal lumen, leading in turn to water secretion and enhanced motility. Some cellular cyclic GMP may be exported and may reduce visceral pain by an action on primary afferent nerves innervating the GI tract (Yu and Rao, 2014).

**Therapeutic Uses and Adverse Effects.** This compound is approved in the treatment of constipation-predominant IBS and chronic constipation in adults at doses of 290 and 145 μg daily, respectively. Common side effects include diarrhea (which can be serious), gas, abdominal pain, and headaches. Linaclotide is contraindicated in children under 6 years old and is not recommended for older children.
Plecanatide. Mechanism of Action and Pharmacology. Plecanatide is a 16-amino acid peptide related to uroguanylin; it has essentially the same mechanism of action as linaclotide.

Therapeutic Uses and Adverse Effects. This agent is approved for the treatment of chronic idiopathic constipation in adults at a dose of 3 mg daily, with or without food. The most common adverse reaction is diarrhea (5%; severe in 0.6%). Plecanatide is contraindicated in children less than 6 years old and not advised in older children up to 18 years of age.

Opioid-Induced Constipation

Opioid analgesics can cause severe constipation. Laxatives and dietary strategies are frequently ineffective in the management of opioid-induced constipation. In addition to lubiprostone, a promising alternative strategy is the prevention of opioid-induced constipation with peripherally acting MOR antagonists that specifically target the underlying reason for this condition, without limiting centrally produced analgesia and limiting the symptoms of opioid withdrawal (Nelson and Camilleri, 2016).

Methylnaltrexone

Mechanism of Action and Pharmacology. The peripherally restricted MOR antagonist methylnaltrexone is approved for the treatment of opioid-induced constipation. The efficacy of this compound has been shown in randomized placebo-controlled trials (Nelson and Camilleri, 2016).

ADME. In patients who respond to the drug, its onset of action is 30–60 min. It is excreted largely unchanged in the urine and feces, but does undergo some hepatic metabolism including sulfation. The time to peak plasma concentration is 30 min and the \( t_{1/2} \) is about 8 h.

Therapeutic Uses and Adverse Effects. Methylnaltrexone is given as a subcutaneous injection (12 mg per day) in adults with chronic noncancer pain after discontinuing other laxatives. In advanced illness (palliative care), dosing varies according to body weight (0.15 mg/kg), with dosing every other day to a maximum of daily injection if required. When administered repeatedly every other day for 2 weeks, bowel movements occurred in about 50% of patients, compared with 8%–15% of patients receiving placebo. Abdominal pain, flatulence, and nausea frequently accompany this treatment. Serious diarrhea sometimes occurs that requires discontinuing therapy. Patients with known or suspected GI obstruction are at increased risk of perforation. Opioid withdrawal may be precipitated in patients with a compromised blood-brain barrier.

Naldemedine

Mechanism of Action and Pharmacology. Naldemedine is a peripherally-restricted opioid antagonist. It is a derivative of naltrexone made more polar and larger in mass with the addition of a side-chain. It is also a substrate for the Pgp efflux transporter. These two properties limit its access to the CNS.

ADME. Following oral administration in the fasted state, naldemedine is rapidly absorbed, reaching peak concentrations in ~45 min. Food prolongs the time to peak (~2.5 h) but does not reduce the overall extent of absorption. Naldemedine is metabolized by hepatic CYP3A and is excreted in both the urine (57%) and feces (35%); its \( t_{1/2} \) is 11 h.

Therapeutic Uses and Adverse Effects. Naldemedine is approved for the treatment of opioid-induced constipation in adult patients with chronic noncancer pain; dose, 0.2 mg/d orally. Common adverse reactions are abdominal pain, diarrhea, nausea, vomiting, and gastroenteritis. Naldemedine is contraindicated in patients with known or suspected obstruction of the GI tract. Opioid withdrawal may be precipitated with the use of this compound (Nelson and Camilleri, 2016).

Naloxegol

Mechanism of Action and Pharmacology. Naloxegol is composed of the MOR antagonist naloxone conjugated to a PEG polymer. This limits blood-brain barrier permeability because it is a substrate for the P-glycoprotein efflux transporter, so it behaves as a peripherally restricted MOR antagonist. It is approved for the treatment of opioid-induced constipation. Randomized placebo-controlled trials have demonstrated the efficacy of this compound (Nelson and Camilleri, 2016).

ADME. The drug is given orally on an empty stomach and is rapidly absorbed. The time to peak plasma concentration is about 2 h with a secondary peak occurring 0.4–3 h after the first. Naloxegol is metabolized primarily by hepatic CYP3A; metabolites are excreted in the feces (68%) and urine (16%). The plasma \( t_{1/2} \) is variable, 6–11 h.

Therapeutic Uses and Adverse Effects. Naloxegol is approved for opioid-induced constipation in adults, given orally 12.5 or 25 mg once per day after discontinuing other laxatives. Diarrhea, abdominal pain, flatulence, and nausea and vomiting are the major adverse reactions. Precautions are the same as for methylnaltrexone: Patients with known or suspected GI obstruction are at increased risk of perforation, and opioid withdrawal may be precipitated in patients with a compromised blood-brain barrier.

Naloxone and Oxycodone

Mechanism of Action and Pharmacology. A fixed-ratio (2:1 of oxycodonenaloxone) combination drug is given orally to relieve opioid-induced constipation when opioid pain relief is still required. The naloxone displaces oxycodone from the MOR in the GI tract without limiting the degree of central analgesia (Nelson and Camilleri, 2016). This combination drug carries with it the risks inherent with all opioids, including addiction and respiratory depression. Full details of this agent are given in Chapter 20.

Therapeutic Uses and Adverse Effects. Naloxone-oxycodone is approved in Canada and other countries for opioid-induced constipation in adults, but currently not for this purpose in the U.S. This oral medication dosing is for pain control and is individualized. A single dose of 40 mg oxycodone/20 mg naloxone every 12 h should not be exceeded. Adverse GI reactions include nausea and vomiting, constipation, and diarrhea.

Other Agents for Opioid-induced Constipation. In clinical trials, the MOR antagonist alvimopan (see separate discussion in the following material) increased spontaneous bowel movements and improved other symptoms of opioid-induced constipation without compromising analgesia. Alvimopan is approved for use in the U.S. for postoperative bowel recovery. However, due to significant cardiovascular adverse events, this drug is not FDA-approved for opioid-induced constipation, and further phase III trials are under way. In addition, the 5HT₄ agonist prucalopride and the GC-C agonist linaclotide (see previous discussion) are in clinical trials for this condition, as are other novel peripherally active MOR antagonists.

Postoperative Ileus

Postoperative ileus refers to the intolerance to oral intake and nonmechanical obstruction of the bowel that occurs after abdominal and nonabdominal surgery. The pathogenesis is complex and is a combination of activation of neural inhibitory reflexes involving sympathetic nerves, enteric MOR, and the activation of local inflammatory mechanisms that reduce smooth muscle contractility (Bragg et al., 2015). The condition is exacerbated by opioids, which are the mainstay of postoperative analgesia. Prokinetic agents typically do not have much effect in this condition, but a new therapeutic agent has been introduced to reduce GI recovery time after surgery.

Alvimopan

Mechanism of Action and Pharmacology. Alvimopan is an orally active, peripherally restricted MOR antagonist that is approved to accelerate the time to upper and lower GI recovery following partial large- or small-bowel resection surgery with primary anastomosis (Curran et al., 2008).

ADME. The drug is hydrolyzed by the gut flora to the active amide. The active metabolite is further metabolized by hepatic glucuronidases. The peak plasma concentration of the active metabolite occurs in about 36 h. The drug’s \( t_{1/2} \) is 10–18 h; the drug is excreted in the urine and feces.

Therapeutic Uses and Adverse Effects. The drug is given 30 min to 5 h prior to surgery (12 mg) and then twice daily for up to a maximum of 7 days or until discharge, not to exceed 15 doses total. Adverse effects include hypokalemia, dyspepsia, and anemia. Because of the risk of myocardial infarctions, this drug is only available through a restricted-access program in the U.S.
Antidiarrheal Agents

Diarrhea: General Principles and Approach to Treatment

Diarrhea (Greek and Latin: dia, “through,” and rhein, “to flow or run”) does not require any definition to people who suffer from “the too rapid evacuation of too fluid stools.” Scientists usually define diarrhea as excessive fluid weight, with 200 g per day representing the upper limit of normal stool weight for healthy adults in the Western world. Because stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

An appreciation and knowledge of the underlying causative processes in diarrhea facilitates effective treatment (Thiagarajah et al., 2015). From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a benign, self-limited illness requiring no treatment or evaluation. Acute diarrhea is frequently due to infection with bacteria, viruses, or protozoa. In more severe cases of diarrhea and in infants and small children, dehydration and electrolyte imbalances are the principal risk. Oral rehydration therapy therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Na+/absorption links to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea in adults should be reserved for patients with significant or persistent symptoms (Menees et al., 2012). Nonspecific antidiarrheal agents typically do not address the underlying pathophysiologic responsible for the diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms.

Empiric Antibiotic Therapy

The use of empiric antibiotic therapy for acute diarrhea (therapy given in the absence of diagnostic evaluation) must be carefully balanced with the risks. In patients with suspected or proven enterohemorrhagic Escherichia coli, antibiotics should be avoided because of the risk of hemolytic uremic syndrome. Similarly, in patients with suspected Clostridium difficile, other antibiotics should be discontinued if possible. Treatment of traveler’s diarrhea, bacterial diarrhea, and those with more severe conditions is appropriate under some conditions, based on the severity of diarrhea and the duration of the symptoms (Steffen et al., 2015). The first-line therapy for acute (most commonly, traveler’s) diarrhea in adults is oral fluoroquinolone antibiotics (see Chapter 56 for specific drug details): ciprofloxacin (500 mg twice daily for up to 3 days), norfloxacin (400 mg twice daily for up to 3 days), ofloxacin (200 mg twice daily for up to 3 days), or levofloxacin (500 mg daily for up to 3 days). Azithromycin (500 mg per day for 1–3 days, or a maximum of 1000-mg single dose) and rifaximin (200 mg three times per day for up to 3 days) are alternative therapeutic agents. Trimethoprim/sulfamethoxazole is also FDA-approved for this use (1 double-strength tab [160/800 mg] twice daily for 5 days). In children, the treatment of traveler’s diarrhea remains controversial. Azithromycin (10 mg/kg to a maximum of 500-mg single dose) is the preferred treatment of children with traveler’s diarrhea.

Bismuth Subsalicylate

Mechanism of Action and Pharmacology. Bismuth compounds are used to treat a variety of GI disorders, although their mechanism of action remains poorly understood (Menees et al., 2012). Bismuth subsalicylate is a popular OTC preparation that consists of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid. Bismuth is thought to have antisecretory, anti-inflammatory, and antimicrobial effects. Bismuth also relieves nausea and abdominal cramps. The clay in bismuth subsalicylate and generic formulations may have some additional benefits in diarrhea, but this is not clear. Bismuth subsalicylate is used for the prevention and treatment of traveler’s diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis.

Therapeutic Uses and Adverse Effects. A recommended dose of the bismuth subsalicylate (30 mL of regular-strength liquid or 2 tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 60 min, as needed, up to eight times a day. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract. Although 99% of the bismuth passes unaltered and unabsobered into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, the product carries the same warning regarding Reye syndrome as other salicylates and may also cause CNS side effects, hearing loss, and tinnitus.

Probiotics

The GI tract contains a vast and complex commensal microflora necessary for health. Alterations in the balance or composition of the microflora are responsible for antibiotic-associated diarrhea and possibly other disease conditions (see Chapter 51). Probiotic preparations containing a variety of bacterial strains have shown some degree of benefit in acute diarrheal conditions, antibiotic-associated diarrhea, and infectious diarrhea (Menees et al., 2012). In clinical trials, preparations containing Lactobacillus GG and Saccharomyces boulardii have been found to be effective for these conditions.

Antimotility and Antisecretory Agents

Opioids. Opioids continue to be widely used in the treatment of diarrhea. They act by several different mechanisms, mediated principally through either MORs or DORs on enteric nerves, epithelial cells, and muscle (see Chapter 20). These mechanisms include effects on intestinal motility (MOR), intestinal secretion (DOR), or absorption (MOR and DOR). Commonly used antidiarrheals such as diphenoxylate, difenoxin, and loperamide act principally via peripheral MOR and are preferred over opioids that penetrate the CNS.

Loperamide. Mechanism of Action and Pharmacology. Loperamide, a compound with MOR activity, is an orally active antidiarrheal agent (Hanauer, 2008; Menees et al., 2012). The drug is 40–50 times more potent than morphine as an antidiarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. Loperamide also increases anal sphincter tone. In addition, loperamide has antisecretory activity against cholera up to eight times a day. Dark stools (sometimes mistaken for melena) and black staining of the tongue, presumably by acting on G1-linked receptors to counter the stimulation of adenyl cyclase activity by the toxins.

ADME. Loperamide is available OTC in capsule, solution, and chewable tablet forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3–5 h. It has a t1/2 of about 11 h and undergoes extensive hepatic metabolism.

Therapeutic Uses and Adverse Effects. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg per day. If clinical improvement in acute diarrhea does not occur within 48 h, loperamide should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2–5 years, 4 mg for ages 6–8 years, and 6 mg for ages 8–12 years. Loperamide is not recommended for use in children younger than 2 years. Loperamide is effective against traveler’s diarrhea,
used alone or in combination with antibiotics. It is used as adjunct treatment in many forms of chronic diarrheal disease (initially as for acute diarrhea, but with typical divided daily doses of 4–8 mg per day), with few adverse effects. Loperamide lacks significant abuse potential and is more effective in treating diarrhea than diphenoxylate. Overdosage, however, can result in constipation, CNS depression (especially in children), and paralytic ileus. In patients with active inflammatory bowel disease involving the colon (see Chapter 51), loperamide should be used with great caution, if at all, to avoid development of toxic megacolon.

**Diphenoxylate and Difenoxin.** Mechanism of Action and Pharmacology. Diphenoxylate and its active metabolite difenoxyn (diphenoxacetic acid) are related structurally to meperidine. As antidiarrheal agents, diphenoxylate and difenoxin are somewhat more potent than morphine (Meneses et al., 2012). Both drugs are listed as schedule V controlled substances by the Drug Enforcement Agency, and both are coformulated with atropine to discourage habituation.

ADME. Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1–2 h. Diphenoxylate is rapidly deesterified to difenoxin, which is eliminated with a t½ of about 12 h.

**Therapeutic Uses and Adverse Effects.** Both drugs are indicated for the treatment of diarrhea. The usual dosage for adults is 2 tablets initially (diphenoxylate or difenoxin), then 1 tablet every 3–4 h, not to exceed 20 mg/d (diphenoxylate) or 8 mg/d (difenoxin). Acute diarrhea usually improves in 48 h if the medication is effective. If chronic diarrhea does not improve within 10 days at the maximum daily dose, then these agents are not likely to be effective. Diphenoxylate is also sold as an oral solution (2.5 mg per 5 mL), which is recommended if used cautiously in children. For children, the initial dose is 0.3–0.4 mg/kg/d in four divided doses to a maximum of 10 mg per day. Once symptoms are controlled, dosing should be reduced; if no effect is seen in 48 h, the drug is unlikely to be effective. Both drugs can produce CNS effects when used in higher doses (40–60 mg per day) and thus have a potential for abuse or addiction. They are available in preparations containing small doses of atropine (considered subtherapeutic) to discourage abuse and deliberate overdosage: 25 μg of atropine sulfate per tablet with either 2.5 mg diphenoxylate hydrochloride or 1 mg of difenoxin hydrochloride. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (nausea, dry mouth, blurred vision, etc.) (see Chapter 9).

**Other Opioids.** Opioids used for diarrhea include codeine (in doses of 30 mg given three or four times daily) and opioid-containing compounds. Paregoric (camphorated opium tincture) contains the equivalent of 2 mg of morphine per 5 mL (0.4 mg/mL); deodorized tincture of opium, which is 25 times stronger, contains the equivalent of 50 mg of morphine per 5 mL (10 mg/mL). The two tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The antidiarrheal dose of opium tincture for adults is 0.6 mL (equivalent to 6 mg morphine) four times daily; the adult dose of paregoric is 5–10 mL (equivalent to 2–4 mg morphine) one to four times daily. Paregoric is used in children at a dose of 0.25–0.5 mL/kg (equivalent to 0.1–0.2 mg morphine/kg) one to four times daily.

**Enkephalins.** Enkephalins are endogenous opioids that are important enteric neurotransmitters; they can inhibit intestinal secretion without affecting motility. Racedoctrool is an example.

**Mechanism of Action and Pharmacology.** Racedoctrool (acetorphin), a prodrug, is rapidly converted in the body to thiopronin, a dipeptide inhibitor of enkephalase (an NEP; EC 3.4.24.11) that does not penetrate into the CNS. By inhibiting peripheral enkephalase degradation, thiopronin potentiates the effects of endogenous enkephalins on the MOR in the GI tract to produce an antidiarrheal effect predominantly as an antisecretory agent (Thiagarajah et al., 2015). In addition to enkephalins, substrates of NEP include neuropeptide Y, atrial and brain natriuretic peptides, substance P, and neurotensins, among others (Erdos and Skidgel, 1989). Thus, inhibition of enkephalase activity could elevate the levels of these messengers as well, complicating interpretation of racedoctrool’s effects on physiological systems.

**Therapeutic Uses and Adverse Effects.** Racedoctrool is indicated for acute diarrhea. It is given orally as a 100 mg initial dose, which is repeated every 8 h as needed until diarrhea stops, for up to 7 days maximum. In children, it is given with oral rehydration solution according to body weight (1.5 mg/kg every 8 h), until symptoms improve or for a maximum of 7 days. This drug is available in many countries, but not the U.S., and is efficacious and safe in children with acute diarrhea. It produces less constipation than loperamide and has minimal other adverse effects (headache, itching).

**α2 Adrenergic Receptor Agonists**

**Mechanism of Action and Pharmacology.** The α2 adrenergic receptor agonists such as clonidine can interact with specific receptors on enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a role for use by diabetics with chronic diarrhea.

**Therapeutic Uses and Adverse Effects.** Oral clonidine (beginning at 0.6 mg three times daily) has been used used in diabetic patients with chronic diarrhea; the use of a topical preparation may result in plasma levels of the drug that are more steady. Clonidine also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients (see Chapter 12 for details of the pharmacology of clonidine).

**Octreotide and Somatostatin**

**Mechanism of Action and Pharmacology.** Octreotide (see Chapter 43) is an octapeptide analogue of SST that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract. Octreotide inhibits secretion of SHT and various GI peptides. Its greatest utility may be in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty, in whom octreotide inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects. Octreotide is widely available; SST is available in some countries, but not the U.S.

**ADME.** Octreotide has a t½ of 1–2 h and is administered either subcutaneously or intravenously as a bolus dose. The time to peak is 0.4 h after subcutaneous injection and 1 h after intramuscular injection. It is metabolized in the liver and excreted in the urine. SST has a plasma t½ of 1–2 min.

**Therapeutic Uses and Adverse Effects.** Standard initial therapy with octreotide is 50–100 μg, given subcutaneously two or three times a day, with titration to a maximum dose of 500 μg three times daily, based on clinical and biochemical responses. A long-acting preparation of octreotide acetate enclosed in biodegradable microspheres is available for use in the treatment of diarrhea associated with carcinoid tumors and VIP-secreting tumors, as well as in the treatment of acromegaly (see Chapter 42). This preparation is injected intramuscularly once per month in a dose of 20 mg. Side effects of octreotide depend on the duration of therapy: Transient nausea, bloating, or pain at sites of injection may occur in the short term, and gallstone formation and hypo- or hyperglycemia may happen in the long term. However, there are also numerous other side effects, including cardiovascular, endocrine, and CNS.

**Variceal Bleeding.** SST and octreotide are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. Octreotide also may act through the ANS. For patients with variceal bleeding, therapy with octreotide usually is initiated while the patient is waiting for endoscopy (a 50-μg bolus dose followed by 50 μg hourly for 2–5 days) (Bhutta and Garcia-Tsao, 2015). Because of its short t½ (1–2 min), SST can be given only by intravenous infusion (a 250-μg bolus dose followed by 250 μg hourly for 2–5 days). Higher doses (up to 500 μg/h) are more efficacious and can be used for patients who continue to bleed on the lower dose.
Intestinal Dysmotility. Octreotide has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, octreotide also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with sclerodermia and small-bowel dysfunction.

Pancreatitis. Both SST and octreotide inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis (Li et al., 2011). The rationale for their use is to rest the pancreas so inflammation by the continuing production of proteolytic enzymes is not aggravated, to reduce intraductal pressures, and to ameliorate pain. However, clinical trials have demonstrated that neither agent is effective in the treatment of acute pancreatitis, although octreotide confers some benefit when given prophylactically to prevent postendoscopic retrograde cholangiopancreatography pancreatitis.

Telotristat Ethyl
Mechanism of Action and Pharmacology. This drug reduces diarrhea associated with carcinoid tumors by inhibiting tryptophan hydroxylase, the rate-limiting enzyme of 5HT biosynthesis. 5HT secretion stimulates fluid secretion and motility in the GI tract.

ADME. Telotristat ethyl is absorbed after oral administration and converted to the active agent Telotristat by the action of carboxylesterases. Peak plasma levels of Telotristat occur 1-3 h after ingestion. Clearance occurs with a t1/2 of 5 h; elimination is via the feces.

Therapeutic Uses and Adverse Effects. Telotristat is given in combination with somatostatin analog therapy for the treatment of diarrhea in carcinoid syndrome. A dose of 250 mg three times/d may be given to adult patients who are not adequately controlled by somatostatin analog therapy alone. The main adverse effects are constipation, nausea, headache, increased gamma glutamyl transferase levels, depression, peripheral edema, flatulence, reduced appetite and, pyrexia.

Berberine
Berberine is a plant alkaloid that has complex pharmacological actions that include antimicrobial effects, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly to treat bacterial diarrhea and cholera but is also apparently effective against intestinal parasites (Menees et al., 2012). The antidiarrheal effects in part may be related to its antimicrobial activity, as well as its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of ACh (by competitive and noncompetitive mechanisms) and blocking the entry of Ca2+ into cells. In addition, it inhibits its intestinal secretion. Berberine is not FDA-approved for use in the U.S.

Bulk-Forming and Hydroscopic Agents
Hydrophilic and poorly fermentable colloids or polymers such as carboxymethylcellulose and calcium polycarbophil absorb water and increase stool bulk (calcium polycarbophil absorbs 60 times its weight in water). They usually are used for constipation but are sometimes useful in acute episodic diarrhea and in mild chronic diarrhea in patients with IBS. Some of these agents also may bind bacterial toxins and bile salts.

Another bulk-forming agent is dextranomer and hyaluronic acid. Dextranomer microspheres are a network of dextran-sucrose beads with exposed hydroxy groups. When this complex is applied to an exudative wound surface, the exudate is drawn by capillary forces generated by the swelling of the beads. The sodium hyaluronate provides viscosity and facilitates injection of the dextranomer. This agent is licensed (as a device) for the treatment of fecal incontinence in adults. It is given as four time 1-mL submucosal injection in the anal canal, which can be repeated after at least 4 weeks if the first treatment is inadequate. The major adverse effects include injection area pain and bleeding.

Bile Acid Sequestrants
Cholestyramine, colesteitol, and colesevelam effectively bind bile acids and some bacterial toxins (Menees et al., 2012). Cholestyramine is useful in the treatment of bile salt–induced diarrhea, as in patients with resection of the distal ileum or after cholecystectomy. In these patients, excessive concentrations of bile salts reach the colon and stimulate water and electrolyte secretion. Patients with extensive ileal resection (usually > 100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of cholestyramine aggravates the diarrhea. In patients having bile salt–induced diarrhea, cholestyramine and colesevelam can be given as an off-label use at a dose of 4–12 g of the dried resin per day. If successful, the dose may be titrated down to achieve the desired stool frequency. The use of these agents is limited by GI side effects, including bloating, flatulence, abdominal discomfort, and constipation.

Crofelemer
Mechanism of Action and Pharmacology. Crofelemer is a purified oligomeric proanthocyanidin from “dragon’s blood,” the reddish latex-like sap of a South American euphorbia. This botanic extract is used for the treatment of diarrhea associated with antiretroviral therapy for HIV/AIDS (Crutchley et al., 2010). It is not approved for infectious or other diarrheas. This drug has minimal systemic absorption and works by inhibiting the cyclic AMP–stimulated CFTR Cl– channel and Ca2+–activated chloride ion channels on the luminal aspect of the enterocyte, thereby reducing the water loss associated with chloride secretion into the lumen.

Therapeutic Uses and Adverse Effects. This drug is given orally (125 mg twice daily) to adults. Infectious diarrhea must be ruled out before treatment. The main adverse effects include upper respiratory tract infections, cough, flatulence, nausea, joint and back pain, and some other GI conditions.

Irritable Bowel Syndrome
Irritable bowel syndrome affects up to 15% of the population in the U.S. and most other Western countries. Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. IBS appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders (Khan and Chang, 2010; Mayer et al., 2014). The disturbances in bowel function can be either constipation or diarrhea or both at different times. Considerable evidence suggests a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological, stimuli in this syndrome (Dekel et al., 2013; Mayer et al., 2014). Many patients can be managed with dietary restrictions, notably by avoiding fermentable oligo-di-mono saccharides and polyols, lactose, or gluten, and fiber supplementation; many cannot. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific, using the agents discussed previously. An important role for serotonin in IBS has been suggested based on its involvement in sensitization of nociceptor neurons in inflammatory conditions and its role in the control of motility and secretion (Dekel et al., 2013). This has led to the development of specific receptor modulators for the treatment of IBS, such as the 5HT3 antagonist alosetron and the 5HT4 agonist prucalopride (see Figure 50–2).

An effective class of agents for IBS has been the tricyclic antidepressants (see Chapter 15), which can have neuromodulatory and analgesic properties independent of their antidepressant effect (Dekel et al., 2013). Tricyclic antidepressants have a proven track record in the management of chronic “functional” visceral pain in adults (off-label use). Amitriptyline, nortriptyline, imipramine, or desipramine can be used at lower doses than those used to treat depression. Starting doses of 10–25 mg amitriptyline, nortriptyline, or imipramine or 12.5–25 mg desipramine at bedtime, should be given for 3–4 weeks because of their delayed onset of action; doses can increased if tolerated and the patient is responsive to treatment. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns. SSRIs (see Chapters 13 and 15) have fewer side effects and have been advocated particularly for patients with functional constipation because SSRIs can increase bowel movements
and even cause diarrhea. However, they probably are not as effective as tricyclic antidepressants in the management of visceral pain. Antidepressant use in children is not strongly supported by clinical trials. α- Adrenergic agonists, such as clonidine (see Chapter 12), also can increase visceral compliance and reduce distention-induced pain.

Alosetron

Mechanism of Action and Pharmacology

The 5HT₃ receptor participates in sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. The clinical effect of 5HT₃ antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. Alosetron, a potent antagonist of the 5HT₃ receptor, was initially withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. Nevertheless, the FDA has reapproved this drug under a limited distribution system for women with severe diarrhea-predominant IBS (Camilleri, 2013). The manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing.

ADME

Alosetron is rapidly absorbed from the GI tract; its duration of action (~10 h) is longer than expected from its t₁/₂ of 1.5 h. It is metabolized by hepatic CYPs and is excreted in the urine and feces.

Therapeutic Uses and Adverse Effects

The drug should be started at 1 mg/d divided into two doses for the first 4 weeks and, if tolerated, advanced to a maximum of 1 mg twice daily if necessary. If the response is inadequate after 4 weeks of 1 mg twice-daily dosing, treatment should be discontinued. The most serious adverse reactions are constellation and ischemic colitis, and therapy must be discontinued immediately in patients who develop those symptoms. Other adverse reactions include nausea and vomiting, GI discomfort and pain, diarrhea, flatulence, hemorrhoids, and others.

Additional 5HT₃ antagonists currently available in the U.S. are approved for nausea and vomiting (see further in this chapter and Chapter 13).

Eluxadoline

Mechanism of Action and Pharmacology

Eluxadoline is a mixed MOR agonist, DOR antagonist, and κ-opioid receptor agonist. It acts locally to reduce abdominal pain and diarrhea without producing constipation in patients with IBS. This opioid drug is FDA approved for the treatment of diarrhea-predominant IBS in adults (Hornby, 2015).

ADME

Eluxadoline’s time to peak C₁ is 1.5–5 h; its t₁/₂ is 3.7–6 h. The route of eluxadoline’s metabolism is not well established; the drug and its metabolic products are excreted in the feces.

Therapeutic Uses and Adverse Effects

In patients with diarrhea-predominant IBS with a gallbladder, the therapeutic dose is 100 mg twice daily with food; the dose may be decreased to 75 mg twice daily in patients unable to tolerate the 100-mg dose. In patients without a gallbladder, eluxadoline is dosed at 75 mg twice daily to reduce the risk of sphincter of Oddi spasm and the potential complication of pancreatitis. Patients with known or suspected biliary duct obstruction, spasticity of Oddi disease or dysfunction, or a history of pancreatitis or structural diseases of the pancreas, should not be given eluxadoline. There are also risks from constipation, and the drug should be discontinued if severe constipation occurs. There is some potential for addiction. The major adverse reactions to the drug are constipation, nausea, and abdominal pain.

Rifaximin

Mechanism of Action and Pharmacology

Antibiotics should not be used routinely in patients with IBS, but the FDA has approved the bacterial RNA synthesis inhibitor rifaximin for diarrhea-predominant IBS (Saadi and McCallum, 2013).

ADME

Rifaximin is well absorbed, with a time to peak less than 1 h. Its t₁/₂ is 6 h; it is cleared by the action of hepatic CYP3A; metabolites are excreted in the feces.

Therapeutic Uses and Adverse Effects

In patients with diarrhea-predominant IBS, the therapeutic dose is 550 mg three times daily for 2 weeks. This regimen may be re-treated twice if symptoms recur. Adverse reactions include nausea, peripheral edema, dizziness, fatigue, and the development of ascites and elevation in serum alanine aminotransferase. If diarrhea worsens after treatment with rifaximin, then an evaluation for development of a severe infectious diarrhea, C. difficile enterocolitis, should be performed.

Antispasmodics

Anticholinergic agents ("spasmolitics" or "antispasmodics") often are used in patients with IBS. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (see Chapter 9) and include the tertiary amines dicyclomine and hyoscyamine and the quaternary ammonium compounds glycopyrrolate and methscopolamine (off-label use). The advantage of the last two compounds is that they have a limited propensity to cross the blood-brain barrier and hence a lower risk for neurological side effects such as light-headedness, drowsiness, or nervousness. These agents typically are given on either an as-needed basis or before meals to prevent the pain and fecal urgency that occur in some patients with IBS.

Dicyclomine is given in 20-mg doses orally every 6 h, increasing to 40 mg every 6 h unless limited by side effects. Hyoscyamine is available as sublingual tablets, orally disintegrating tablets, immediate-release oral capsules, tablets, elixir, and drops (all administered as 0.125–0.25 mg every 4 h as needed) and extended-release forms for oral use (0.25–0.375 mg every 12 h, or 0.375 mg every 8 h, as needed), and as an injection for intramuscular, intravenous, or subcutaneous use (0.25–0.5 mg every 4 h as needed). Glycopyrrolate is rarely used but is available as immediate-release tablets, as an oral solution, and as an injectable; the oral dose is 1–2 mg two or three times daily, not to exceed 6 mg/d. Methscopolamine is provided as 2.5-mg and 5-mg tablets; the dose is 2.5 mg a half hour before meals and 2.5–5 mg at bedtime.

Other Drugs

Cimetropium and acebtiamide are muscarinic antagonists that are effective in patients with IBS but are not available in the U.S. Acebtiamide appears to be a promising agent for the treatment of postprandial distress syndrome, one of two major forms of functional dyspepsia (Zala et al., 2015). Ottolium bromide is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca²⁺ channels and neurokinin NK₁ receptors; it is not available in the U.S. Mebeverine hydrochloride, a derivative of hydroxybenzamide, appears to have a direct effect on the smooth muscle cell, blocking K⁺, Na⁺, and Ca²⁺ channels. Mebeverine is used outside the U.S. as an antispasmodic agent. It is given orally, 100–135 mg three times daily or 200 mg twice daily, before meals.

Antinauseants and Antiemetics

Nausea and Vomiting

**Nausea and Vomiting**

*Emesis* and the sensation of *nausea* that frequently accompanies it are generally viewed as components of a protective reflex that serve to rid the stomach and intestine of toxic substances (emesis) and prevent their further ingestion (*nausea* serves as an unconditioned aversive stimulus for learning and memory) (Horn, 2008; Hornby, 2001). *Vomiting* is a complex process that appears to be coordinated by a central emesis center in the lateral reticular formation of the midbrainstem adjacent to both the CTZ in the area postrema on the floor of the fourth ventricle and the STN. The lack of a blood-brain barrier at the CTZ permits monitoring of blood and cerebrospinal fluid constantly for toxic substances and
Figure 50–5 Pharmacologist’s view of emetic stimuli. Many signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in italics. These pathways involve specific neurotransmitters and their receptors (bold type). Receptors are shown for dopamine (D), ACh (muscarinic, M), histamine (H), cannabinoids (CB), substance P (NK), and 5HT. Some of these receptors also may mediate signaling in the emetic center.

*The most effective agents for chemotherapy-induced nausea and vomiting are the SHT receptor antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy and reduce incidence of side effects. See Table 50–5.

1/2 also has some peripheral activity at SHT receptors.

1/2 Also has some antihistaminic and anticholinergic activity.

receptor affinity, a longer 1/2, and demonstrated superiority over first-generation antagonists (Navari, 2014).

The SHT receptor agonists are present in several critical sites involved in emesis, including vagal afferents, the STN (which receives signals from vagal afferents), and the area postrema itself (see Figure 50–5). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and stimulates vagal afferents (via SHT receptors) to initiate the vomiting reflex. The highest concentrations of SHT receptors in the
**TABLE 50–5** | **ANTIEMETIC AGENTS IN CANCER CHEMOTHERAPYA**

| Low risk of emesis: | Prechemotherapy
|--------------------|-----------------
| • Dexamethasone | • Metoclopramide ± diphenhydramine
| • Ondansetron | • Dolasetron (not approved in the U.S.)
| • Granisetron | • Palonosetron
| Postchemotherapy (delayed emesis) | (delayed emesis)
| Prechemotherapy | Postchemotherapy (delayed emesis)
| • Aprepitant (days 2 and 3) | Dexamethasone + aprepitant
| • Dexamethasone or 5HT3 antagonist (days 2–3 or 4) | Dexamethasone (days 2–4) ± loriapazem (days 2–4)
| Aprepitant (days 2–3, if used prechemo) ± dexamethasone (days 2–4) | ± lorazepam (days 2–4)

**Moderate risk of emesis:**

| Prechemotherapy | 5HT3 antagonist + dexamethasone
| Prechemotherapy | 5HT3 antagonist + dolasetron + NK antagonist
| Postchemotherapy | Dexamethasone + aprepitant
| Postchemotherapy | Dexamethasone (days 2–4) + aprepitant (days 2 and 3) ± lorazepam (days 2–4)

**High risk of emesis:**

| Prechemotherapy | 5HT3 antagonist + dexamethasone + NK antagonist ± loriapazem
| Prechemotherapy | 5HT3 antagonist/NK, antagonist + dexamethasone
| Postchemotherapy (delayed emesis) | Dexamethasone + aprepitant
| Postchemotherapy (delayed emesis) | Dexamethasone ± aprepitant

*Specific recommendations and doses are tailored to the patient and the chemotherapeutic regimen. For updated information, see the National Cancer Institute website (see Cancer Topics: Nausea and Vomiting). Some patients profit from cannabinoids (dronabinol, nabulone) with or without a phentothiazine or dexamethasone.

**ADME.** These agents are absorbed well from the GI tract and have a rapid onset of action. Ondansetron is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. The \( t_{1/2} \) is 3–6 h. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. Granisetron also is metabolized predominantly by the liver by the CYP3A family and has a \( t_{1/2} \) of 6–9 h, depending on the route of administration. Dolasetron is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver, while about one-third of it is excreted unchanged in the urine. The \( t_{1/2} \) of the active metabolite hydrodolasetron is 6–8 h. Palonosetron is metabolized principally by CYP2D6; the metabolized and the unchanged forms are excreted in the urine in roughly equal proportions. The \( t_{1/2} \) after intravenous injection is about 40 h in adults. The antiemetic effects of these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level; these drugs can be administered effectively just once a day.

**Therapeutic Uses and Adverse Effects.** These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation. They also are effective against hyperemesis of pregnancy and, to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, palonosetron may be helpful in delayed emesis, perhaps reflecting its long \( t_{1/2} \). These agents are available as tablets, oral solution, and intravenous preparations for injection. Palonosetron, in combination with the NK, receptor antagonist netupitant (see further discussion), is FDA approved for the treatment of acute and delayed nausea and vomiting. This combination is highly effective when combined with the corticosteroid dexamethasone (see further discussion). For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 50–6) infused over 15 min, beginning 30 min before chemotherapy, or in two or three divided doses, with the first usually given 30 min before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly (ondansetron only) or orally. Granisetron is available as a transdermal formulation that is applied 24–48 h before chemotherapy and worn for up to 7 days.

In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and light-headedness. Electrocardiogram interval changes (QT prolongation) are a feature of the first-generation antagonists; the injectable form of dolasetron is contraindicated for prophylactic therapy for chemotherapy-induced nausea and vomiting. The oral form is associated with a lower risk, but risk is still present. Palonosetron does not appear to increase QT intervals (Gonullu et al., 2012). These drugs have also been associated with serotonin syndrome and should be used cautiously if patients are taking other medications, such as SSRIs, that could increase 5HT levels.

**Dopamine Receptor Antagonists**

**Mechanism of Action and Pharmacology.** The principal mechanism of action of dopamine receptor antagonists is D2 receptor antagonism at the CTZ, reducing excitatory neurotransmitter release (Andrews and Sanger, 2014; Kovac, 2013).

**Phenothiazines.** Prochlorperazine, and to a lesser extent chlorpromazine (see Chapter 16), are among the most commonly used “general-purpose” antiemetics and antiemetics in adults and children. These drugs are not uniformly effective in cancer chemotherapy-induced emesis, but they possess antihistaminic and anticholinergic activities that are of value in other forms of nausea and vomiting, such as motion sickness and that of GI origin. These drugs are available as tablets, injectables, or suppositories. Typical dosing of prochlorperazine is 5–10 mg orally every 6–8 h, 5–10 mg intramuscularly, or 2.5 mg to 10 mg intravenously every 3–4 h (maximum 40 mg/d), or 25 mg rectally every 12 h. The main adverse effects are extrapyramidal reactions, including dystonia, cardiac effects, and hypotension. These drugs are contraindicated due to increased mortality in elderly patients with dementia-related psychosis.

**Benzamides.** The prokinetic benzamide agents (see previous discussion) are moderately useful antiemetics, but are no longer the drugs of choice for acute chemotherapy-induced nausea and vomiting due to their lack of efficacy and side-effect profile. However, the antiemetic actions add to their value in the treatment of GI motor disturbances, and metoclopramide is a useful treatment of delayed emesis.

*Trimethobenzamide* is given for gastroenteritis and postoperative nausea and vomiting (orally at doses of 300 mg every 6 h or 200 mg IM).

**Olanzapine.** Olanzapine is an atypical (second-generation) antipsychotic that is a dopamine (D<sub>2</sub>) and 5HT<sub>3</sub> receptor antagonist (see Chapter 16). It is an effective agent for the prevention of chemotherapy-associated delayed nausea or vomiting (off-label use; used in combination with a corticosteroid and 5HT<sub>3</sub> antagonist) (Fonte et al., 2015). It is also gaining attention for the treatment of refractory non–chemotherapy-induced nausea and vomiting. It is given orally, 10 mg once daily for 3 to 5 days, beginning on day 1 of chemotherapy or 5 mg once daily for 2 days before chemotherapy, followed by 10 mg once daily (beginning on the day of chemotherapy) for 3 to 8 days. The adverse reactions are extensive and include many CNS, cardiovascular, and metabolic side effects that are described in Chapter 16.

**Antihistamines**

Histamine H<sub>1</sub> antagonists are primarily useful for motion sickness and postoperative emesis. They act on vestibular afferents and within the brainstem. **Cyclizine, meclizine, promethazine,** and **diphenhydramine** are examples of this class of agents. **Cyclizine** has additional anticholinergic effects that may be useful for patients with abdominal cancer. Sedation is always a common side effect of these drugs. For a detailed discussion of these drugs, see Chapter 39.

**Anticholinergic Agents**

The most commonly used muscarinic receptor antagonist for motion sickness is **scopolamine** (hyosine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (1.5 mg every 3 days). Its principal utility is in the prevention and treatment of motion sickness, with some activity in postoperative nausea and vomiting. In general, however, anticholinergic agents have no role in chemotherapy-induced nausea. The principle side effects are dry mouth, visual disturbances, and drowsiness.

**Neurokinin Receptor Antagonists**

**Mechanism of Action and Pharmacology.** The nausea and vomiting associated with emetogenic chemotherapy (see Chapter 65) has two components: an acute phase that universally is experienced (within 24 h after chemotherapy) and a delayed phase that affects only some patients (on days 2–5). **SHT**<sub>3</sub> receptor antagonists are not very effective against delayed emesis. However, antagonists of the NK<sub>1</sub> receptors, the receptors for the neuropeptide substance P, such as **aprepitant** (and its parenteral formulation fosaprepitant), have antiemetic effects in delayed nausea and improve the efficacy of standard antiemetic regimens in patients receiving multiple cycles of chemotherapy (Aapro et al., 2015). A new, highly selective NK<sub>1</sub> antagonist, **rolapitant**, with an exceptionally long plasma t<sub>1/2</sub> (180 h) was FDA approved in September 2015 for prevention of chemotherapy-induced delayed emesis.

**Aprepitant.** The NK<sub>1</sub> antagonist aprepitant is typically given with a 5HT<sub>3</sub> antagonist and dexamethasone.

**ADME.** After absorption, **aprepitant** is bound extensively to plasma proteins (>95%); it is metabolized primarily by hepatic CYP3A4 and is excreted in the stools; its t<sub>1/2</sub> is 9–13 h. **Aprepitant** has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including dexamethasone, methylprednisolone (whose dose may need to be reduced by 50%), and warfarin.

**Therapeutic Uses and Adverse Effects.** **Aprepitant** is contraindicated in patients on cisapride or pimozide, in whom life-threatening QT prolongation has been reported. **Aprepitant** is supplied in 40-, 80-, and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy, along with a 5HT<sub>3</sub> antagonist and a corticosteroid. The injectable form, fosaprepitant, in a dose of 115 mg, may be substituted for the first dose of aprepitant at the start of the 3-day regimen. The recommended adult dosage of aprepitant is 125 mg administered 1 h before chemotherapy on day 1, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen.

**Rolapitant.** Rolapitant is a potent NK<sub>1</sub> receptor antagonist that is administered with a 5HT<sub>3</sub> antagonist and dexamethasone to help prevent delayed phase chemotherapy-induced nausea and vomiting.

**ADME.** After a single oral dose of 180 mg, rolapitant is well absorbed with peak C<sub>p</sub> at 4 h and t<sub>1/2</sub> at about 180 h. **Rolapitant** is metabolized primarily by CYP3A4 to form an active metabolite, M19 (C4-pyridolinedeoxyxylated rolapitant). M19 has a t<sub>1/2</sub> of about 158 h. Rolapitant is eliminated mainly via the hepatic/biliary route.

**Therapeutic Uses and Adverse Effects.** A single 180-mg dose is administered orally 1–2 h prior to chemotherapy (together with 5HT<sub>3</sub> antagonist and dexamethasone). The adverse effects include neutropenia, hiccups, decreased appetite, and dizziness. **Rolapitant** is a moderate inhibitor of CYP2D6 and of the Pgp and BCRP transporters. **Rolapitant** is contraindicated in patients receiving drugs that are CYP2D6 substrates, such as thioridazine or pimozide. A significant increase in plasma concentrations of thioridazine may result in QT prolongation and torsades de pointes.

**Netupitant and Palonosetron Combination.** A combination NK<sub>1</sub> receptor antagonist plus 5HT<sub>3</sub> receptor antagonist (netupitant and palonosetron) was recently approved (Abramovitz and Gaertner, 2016).

**ADME.** This combination is well absorbed; the drugs have a similar time to peak C<sub>p</sub> (5 h) and very long half-lives (netupitant, ~ 80 h; palonosetron, ~ 48 h). They are excreted in the feces and urine. **Netupitant** is extensively metabolized by CYP3A4 (major) and CYP2C9 and CYP2D6 (minor) to active metabolites. **Palonosetron** is about 50% metabolized in the liver to inactive metabolites.

**Therapeutic Uses and Adverse Effects.** A single capsule is administered orally about 1 h prior to chemotherapy (together with dexamethasone, at doses varying according to the type of chemotherapy). The adverse effects are the same as for the 5HT<sub>3</sub> antagonists (see previous discussion).

**Cannabinoids**

**Dronabinol. Mechanism of Action and Pharmacology.** Dronabinol (Δ<sub>9</sub>-tetrahydrocannabinol) is a naturally occurring cannabinoid that can be synthesized chemically or extracted from the marijuana plant, *Cannabis sativa*. The mechanism of the antiemetic action of dronabinol is related to stimulation of the CB<sub>2</sub> subtype of cannabinoid receptors on neurons in and around the CTZ and emetic center (see Figure 50–5) (Sharkey et al., 2014).

**ADME.** Dronabinol is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2–4 h. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10%–20%). The principal active metabolite is 11-OH-Δ<sub>9</sub>-tetrahydrocannabinol. These metabolites are excreted primarily via the biliary-fecal route, with only 10%–15% excreted in the urine. Both dronabinol and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of dronabinol can result in detectable levels of metabolites for several weeks.

**Therapeutic Uses and Adverse Effects.** Dronabinol is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. It also can stimulate appetite and has been used in patients with AIDS and anorexia. As an antiemetic agent, it is administered at an initial dose of 5 mg/m<sup>2</sup> given 1–3 h before chemotherapy and then every 2–4 h afterward for a total of four to six doses. If this is inadequate, incremental increases can be made up to a maximum of 15 mg/m<sup>2</sup> per dose. For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to a maximum of 20 mg per day.
Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like "highs" (e.g., euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and abnormalities of thinking. After abrupt withdrawal of dronabinol, an abstinence syndrome (irritability, insomnia, and restlessness) can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it also may be abused by these patients.

**Nabilone. Mechanism of Action and Pharmacology.** Nabilone is a synthetic cannabinoid with a mode of action similar to that of dronabinol.

**ADME.** Nabilone is a highly lipid-soluble compound that is rapidly absorbed after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 h. The t1/2 is about 2 h for the parent compound and 35 h for metabolites. The metabolites are excreted primarily via the biliary-fecal route (60%), with about 25% excreted in the urine.

**Therapeutic Uses and Adverse Effects.** Nabilone is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. A dose (1–2 mg) can be given the night before chemotherapy; usual dosing starts 1–3 h before treatment and then every 8–12 h during the course of chemotherapy and for 2 days following its cessation. The adverse effects are largely the same as for dronabinol, with significant CNS actions in more than 10% of patients. Cardiovascular, GI, and other side effects are also common and, together with the CNS actions, limit the usefulness of this agent.

**Glucocorticoids and Anti-inflammatory Agents**

Glucocorticoids such as dexamethasone can be useful adjuncts (see Table 50–5) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of NSAIDs in the nausea and vomiting induced by systemic irradiation (Chu et al., 2014). For a detailed discussion of these drugs, see Chapters 38 and 46.

**Benzodiazepines**

Benzodiazepines, such as lorazepam and alprazolam, by themselves are not very effective antiemetics, but their sedative, amnesic, and antianxiety effects can be helpful in reducing the anticipatory component of nausea and vomiting in patients. For a detailed discussion of these drugs, see Chapter 19.

**Phosphorated Carbohydrate Solutions**

Aqueous OTC solutions of glucose, fructose, and orthophosphoric are available to relieve nausea. These solutions are given orally (15–30 mL, adults; 5–10 mL, children; repeated every 15 min until the symptoms alleviate. No more than five doses may be taken). Their mechanisms of action are unclear.

**Doxylamine Succinate and Pyridoxine**

**Mechanism of Action and Pharmacology.** Nausea commonly occurs in the early stages of pregnancy. This may or may not be accompanied by vomiting. The management of this condition depends of the severity of symptoms, which usually resolve by midpregnancy regardless of their severity. **Pyridoxine** (vitamin B6) improves mild-to-moderate nausea and its efficacy is improved when it is combined with the histamine H1 antagonist doxylamine (Fantasia, 2014). Considering the caveats associated with the use of antiemetics medications during early pregnancy, readers may wish to review the history of this drug combination; see the work of Slaughter et al., 2014.

**ADME.** Doxylamine is metabolized in the liver by N-dealkylation. It has a t1/2 of 10–12 h and is excreted in the urine. **Pyridoxine** is well absorbed and has a t1/2 of 2–3 weeks.

**Therapeutic Uses and Adverse Effects.** This drug-vitamin combination is given for the treatment of nausea and vomiting of pregnancy. Initially, 2 delayed-release tablets (a total of doxylamine 20 mg and pyridoxine 20 mg) are taken at bedtime. The dose may be increased to 4 tablets per day as needed for more severe nausea (1 tablet in the morning, 1 tablet in the afternoon, 2 tablets at bedtime). The major side effects of this drug include drowsiness, dry mouth, light-headedness, and constipation.

**Miscellaneous GI Disorders**

**Cystic Fibrosis, Chronic Pancreatitis, and Steatorrhea**

**Pancreatic Enzymes**

**Chronic pancreatitis** is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). The goals of pharmacological therapy are prevention of malabsorption and palliation of pain (Trang et al., 2014). **Cystic fibrosis** is a genetic disorder that affects exocrine secretion. Exocrine pancreatic insufficiency occurs in the majority of patients with more severe forms of cystic fibrosis. Pharmacological therapy is used to treat these patients (Somaraju and Solis-Moya, 2014).

**Enzyme Formulations.** Pancreatic enzymes (lipase, amylase, and proteases) are secreted together; hence, lipase can be used to titrate the doses of pancreatic enzyme supplements, which are typically prescribed on the basis of the lipase content. Only pancreatic lipase is licensed for sale in the U.S. Pancrelipase products, of which there are six on the market, differ in their content of lipase, protease, and amylase and thus may not be interchangeable.

**Replacement Therapy for Malabsorption.** Fat malabsorption (steatorrhea) and protein maldigestion occur when the pancreas loses more than 90% of its ability to produce digestive enzymes. This occurs in chronic pancreatitis, following pancreatectomy, or in cystic fibrosis. The resultant diarrhea and malabsorption can be managed well if 90,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-h period with and after meals. Alternatively, one can titrate the dosage to the fat content of the diet, with about 8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes contain 3000–40,000 USP units of lipase, 10,000–136,000 USP units of protease, and 15,000–218,000 USP units of amylase. In adults and children over 4 years, the initial dose of lipase is 500 USP units/kg/meal, increasing up to 2500 USP units/kg/meal. Children younger than 4 have increased needs for lipase, and initial doses are higher. There are also special dosing regimens for breastfeeding infants. In all cases, lipase dosing should not exceed maximum recommendations and generally should not exceed 2500 USP units/kg/meal or 10,000 USP units/kg/d.

**Enzymes for Pain.** Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative-feedback inhibition of the pancreas by the presence of duodenal proteases. The release of CCK, the principal secretagogue for pancreatic enzymes, is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

**Adverse Effects.** Despite the fact that the enzymes are not absorbed and are excreted in feces, there are adverse effects, which include headache and abdominal pain; however, pancreatic enzyme preparations are tolerated extremely well by patients. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.
Gallstones and Primary Biliary Cirrhosis

Bile Acids

Bile acids and their conjugates are synthesized from cholesterol in the liver. Bile acids induce bile flow, feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the emulsification and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine, returned to the liver, and then again secreted in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids; lithocholic acid and ursocholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called sodium salts.

Traditional therapy for gallstones involves oral litholysis with ursocholic acid (ursodiol), but there is now evidence that inhibiting cholesterol synthesis (with statins) or intestinal cholesterol absorption (with ezetimibe) may have some beneficial effects to reduce gallstone formation (Portincasa et al., 2012). As for the treatment of gallstones, treatment for primary biliary cirrhosis also involve the use of ursocholic acid. New therapies are being developed that include obeticholic acid, a semisynthetic analogue of chenodeoxycholic acid, an endogenous ligand of the farnesoid X receptor (a nuclear receptor important for regulating bile acid and cholesterol metabolism), and treatment with farnesoid x receptor activator obeticholic acid. Another promising therapy includes combining ursocholic acid with the steroid budesonide (see Chapter 46) for the treatment of early-stage primary biliary cirrhosis (Tabibian and Lindor, 2015).

Ursodeoxycholic acid (ursodiol) (Figure 50–6) is a hydrophilic, deoxyxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid (chenodiol) in the gut by intestinal bacteria. Ursodiol is given for the prevention and treatment of gallstones and for the treatment of primary biliary cirrhosis (Portincasa et al., 2012; Tabibian and Lindor, 2015). When administered orally, litholytic bile acids such as chenodiol and ursodiol alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. Ursodiol also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases. For gallstone treatment, it is given orally 8–10 mg/kg/d in divided doses, for gallstone prevention 300 mg twice daily, and for primary biliary cirrhosis 13–15 mg/kg/d in two to four divided doses with food. Adverse effects at these doses are generally uncommon, but include headache, GI disturbances, and nausea. At higher-than-recommended doses, there may be serious adverse effects of ursodiol. Dissolution of gallstones by chenodiol is reserved for patients who are at increased surgical risk and have radiolucent stones.

Flatulence

“Gas” is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation but also bloating or fullness. OTC and herbal preparations are popular. Simethicone, a mixture of siloxane polymers stabilized with silicon dioxide, is an inert nontoxic, insoluble liquid. Because of its capacity to collapse bubbles by forming a thin layer on their surface, it is an effective antifoaming agent; whether this accomplishes a therapeutic effect in the GI tract is not clear. Simethicone is available in chewable tablets, liquid-filled capsules, suspensions, and orally disintegrating strips, either by itself or in combination with other OTC medications, including antacids and other digestants. The usual dosage in adults is 40–125 mg four times daily after meals; the pediatric dose is 20–50 mg four times daily after meals and at bedtime, depending on the age of the child. Activated charcoal may be used alone or in combination with simethicone but has not been shown conclusively to have much benefit. An α-galactosidase OTC preparation is available to reduce gas from baked beans.

Short-Bowel Syndrome

Short-bowel syndrome is a malabsorption disorder caused by removal of the small intestine or rarely because of a congenital bowel abnormality. Short-bowel syndrome requires total parenteral nutrition, and treatments are aimed at reducing the need for this, including supplemented specialized diets and implementing a therapy based on physiologic principles of the actions of gut hormones.

Teduglutide

Mechanism of Action and Pharmacology. The gut hormone GLP-2 is secreted by L cells of the ileum and colon and is the only intestinotrophic gut peptide. Among other actions, it enhances growth of the intestinal mucosa through the release of mediators, including insulin-like growth factor 1. Teduglutide is a 33–amino acid GLP-2 analogue recently approved for the treatment of short-bowel syndrome (Jeppesen, 2015).

ADME. The drug has a t½ of 1–2 h and is excreted in the urine. It is catalyzed by dipeptidyl pep tidease 4, but more slowly than the native peptide because of the substituted amino acid structure.

Therapeutic Uses and Adverse Effects. Teduglutide is administered subcutaneously once daily (0.05 mg/kg) to help improve intestinal absorption of nutrients and thereby reduce the need for parenteral support. Common side effects include abdominal pain, nausea, headache, and flu-like symptoms. There is also the potential for teduglutide to cause cancer of the bowel; therefore, it is not recommended for patients with active malignancies.

PEDIATRIC IBD

THERAPY OF IBD DURING PREGNANCY

Inflammatory Bowel Disease

Inflammatory bowel disease is a spectrum of remitting and relapsing, chronic, inflammatory intestinal conditions. IBD causes significant GI symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD conventionally is divided into two major subtypes: ulcerative colitis and Crohn disease.

Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis) (Ordas et al., 2012). Crohn disease, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve (Sartor, 2006). The inflammation in Crohn disease is not necessarily confluent, frequently leaving "skip areas" of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or fistula formation. IBD is often associated with extraintestinal manifestations involving the joints, skin, or eyes (Ott and Scholmerich, 2013). Primary sclerosing cholangitis is a serious but infrequent complication of ulcerative colitis in which inflammation and fibrostenosis occurs in the intra- and extrahepatic biliary tree (Williamson and Chapman, 2014). Chronic, severe IBD is associated with an increased risk for the development of colorectal cancer (Beaugerie and Itzkowitz, 2015).

Pathogenesis of IBD

A summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 51–1. Both diseases are associated with an aberrant immune response to the commensal microbiota of the gut in genetically susceptible individuals (Sartor, 2006). Recent evidence of dysbiosis of the microbiome in IBD supports this theory (Bellaguarda and Chang, 2015). Nevertheless, Crohn disease and ulcerative colitis result from distinct pathogenic mechanisms at the level of mucosal immune activation (Xavier and Podolsky, 2007). Histologically, the transmural lesions in Crohn disease exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in ulcerative colitis have lymphocytic and neutrophilic infiltrates.

Our understanding of the pathogenesis of both Crohn disease and ulcerative colitis has increased dramatically in recent years (Kaser et al., 2010). Within the diseased bowel in Crohn disease, the cytokine profile includes increased levels of IL-12, IL-23, IFN-γ, and TNF-α, findings characteristic of T\textsubscript{n}1-mediated inflammatory processes. In contrast, the inflammatory response in ulcerative colitis resembles aspects of that mediated by the T\textsubscript{n}2 pathway. Understanding of the inflammatory processes has evolved with the description of regulatory T cells and pro-inflammatory T\textsubscript{n}17 cells, a novel T-cell population that expresses IL-23 receptor as a surface marker and produces, among others, the pro-inflammatory cytokines IL-17, IL-21, IL-22, and IL-26. T\textsubscript{n}17 cells seem to play a prominent role in intestinal inflammation, particularly in Crohn disease.

Medical therapy for IBD is problematic. Because of the multifactorial nature of disease etiology, current therapy for IBD seeks to dampen the generalized inflammatory response. Regrettably, no agent can reliably accomplish this, and the response of an individual patient to a given drug may be limited and unpredictable. Recently, mucosal healing has become an important therapeutic aim, as opposed to simply the relief of symptoms (Florholmen, 2015). Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications, such as fistulas (D’Haens et al., 2014). The major therapeutic options are considered in the following material.

Classifications of Drugs to Treat IBD

Mesalamine-Based Therapy

First-line therapy for mild-to-moderate ulcerative colitis generally involves 5-ASA (Bressler et al., 2015). 5-ASA-based treatments have largely been abandoned in maintenance of remission Crohn disease (Sandborn et al., 2007) due to the fact that their anti-inflammatory effects are targeted topically to the mucosa, with limited effects on deeper inflammation, which has implications for long-term outcomes. The archetype for this class of medications is sulfasalazine, which consists of 5-ASA linked to sulfapyridine by an azo bond (Figure 51–2).

Mechanism of Action, Pharmacological Properties, and Therapeutic Uses

Sulfasalazine is an oral produg that effectively delivers 5-ASA to the distal GI tract (Figure 51–3). The azo linkage in sulfasalazine prevents absorption in the stomach and small intestine, and the individual components are not liberated until colonic bacterial azoreductases cleave the bond for local effect (Peppercorn and Goldman, 1972). 5-ASA is the therapeutic moiety, with little, if any, contribution by sulfapyridine, a sulfonamide antibiotic. Although 5-ASA is a salicylate and can block COX, its mode of action does not appear to involve this activity; indeed, traditional NSAIDs
may exacerbate IBD and are strongly contraindicated. Many potential sites of action (effects on immune function and inflammation) have been demonstrated in vitro for sulfasalazine and mesalamine (Perrotta et al., 2015), including inhibition of the production of IL-1 and TNF-α, inhibition of the lipooxygenase pathway, scavenging of free radicals and oxidants, the inhibition of NF-κB, a transcription factor pivotal to production of inflammatory mediators. However, specific mechanisms of action underlying the efficacy of sulfasalazine/5-ASA in IBD have not been identified.

To preserve the therapeutic effect of 5-ASA without the adverse effects of sulfapyridine, several second-generation 5-ASA compounds have been developed. They are divided into two groups: prodrugs and coated drugs. Prodrugs contain the same azo bond as sulfasalazine but replace the linked sulfapyridine with either another 5-ASA (oscloazine) or an inert compound (balsalazide) (Jain et al., 2006). The alternative approaches employ mesalamine directly, using either a delayed-release formulation or a pH-sensitive coating. Delayed-release mesalamine releases drug throughout the GI tract, whereas pH-sensitive mesalamine is released in the small intestine and colon. These different distributions of drug delivery have potential therapeutic implications (Figure 51–4).

Oral sulfasalazine is effective in patients with mild or moderately active ulcerative colitis, with response rates of 60%–80%. The usual dose is 4 g/d in four divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/d can be used but cause an increased incidence of side effects. For patients with severe colitis, sulfasalazine is of less certain value, even though it is often added as an adjunct to systemic glucocorticoids. The drug plays a useful role in preventing relapses once remission has been achieved. Because they lack the dose-related side effects of sulfapyridine, the delayed- and pH-dependent formulations can be used to deliver mesalamine with improved safety and tolerability. The doses of mesalamine used to treat active disease are 2.4–4.8 g/d for up to 8 weeks, and current practice is to administer 5-ASA as a once-daily dose, which is as effective as a multiple daily dosing regimen (Feagan and Macdonald, 2012).

Topical preparations of mesalamine suspended in a wax matrix suppository or in a suspension enema are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical hydrocortisone in this setting, with response rates of 75%–90%. Mesalamine enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 h; the suppository (500 and 1000 mg) should be used two to three times a day with the objective of retaining it for at least 3 h. Response to local therapy with mesalamine may occur within 7–14 days; however, the usual course of therapy is from 8 to 16 weeks for induction of remission. Once remission has occurred, lower doses can be considered for maintenance, although increasingly the dose used for induction is continued for maintenance.

ADME

The pharmacokinetics of 5-ASA–based drugs are well described (Sandborn and Hanauer, 2003). About 20%–30% of orally administered sulfasalazine (mesalamine prodrug) is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg mesalamine for every gram of the parent compound. Thereafter, the individual components of sulfasalazine follow different metabolic pathways. Sulfapyridine is absorbed rapidly from the colon and undergoes extensive hepatic metabolism, including acetylation and hydroxylation, and conjugation with glucuronic acid, prior to excretion in the urine. The acetylation phenotype of the patient determines plasma levels of sulfapyridine and the probability of side effects; rapid acetylators have lower systemic levels of the drug and fewer adverse effects. Only 25% of mesalamine is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and liver and then excreted in the urine. Intraluminal concentrations of mesalamine therefore are very high (~1500 μg/mL).

The pH-sensitive coatings limit gastric and small intestinal absorption of mesalamine. The pharmacokinetics of delayed-release formulations differ somewhat. The ethylcellulose-coated microgranules are released in the upper GI tract as discrete prolonged-release units of mesalamine. Acetylated mesalamine can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, although some intact microgranules can later be detected in the colon. Because the delayed-release drug is released in the small bowel, a greater fraction of the 5-ASA in the delayed-release formulations is absorbed systemically compared with the other 5-ASA preparations.

Adverse Effects

Side effects of sulfasalazine occur in 10%–45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose related, including headache, nausea, and fatigue; these can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. Sulfasalazine reversibly decreases the number and motility of sperm but does not impair female fertility. Sulfasalazine inhibits intestinal folate absorption and is usually administered with folate. Mesalamine formulations generally are well tolerated. Headache, dyspepsia, and skin rash are the most common side effects. Diarrhea appears to be particularly common with olsalazine (occurring in 10%–20% of patients). Nephrotoxicity, although rare, is a more serious concern. Mesalamine has been associated with interstitial nephritis; renal function should be monitored in all patients receiving these drugs.

Both sulfasalazine and its metabolites cross the placenta but have not been shown to harm the fetus. The newer formulations also appear to be safe in pregnancy, but there have been some safety concerns about dibutyl phthalate, an inactive ingredient in the coating of some formulations, in the context of pregnancy.

Glucocorticoids

The glucocorticoids cortisone, dexamethasone, prednisolone, and triamcinolone are all FDA approved for the treatment of IBD.

Mechanism of Action, Pharmacological Properties, and Therapeutic Uses

The effects of glucocorticoids on the inflammatory response are numerous (see Chapters 42 and 46). Glucocorticoids are indicated for

Abbreviations

APC: antigen-presenting cell
5-ASA: 5-aminosalicylic acid, mesalamine
COX: cyclooxygenase
FDA: Food and Drug Administration
GI: gastrointestinal
HPGRt: hypoxanthine-guanine phosphoribosyl transferase
HPA: hypothalamic-pituitary-adrenal (axis)
IBD: inflammatory bowel disease
IFN: interferon
IL: interleukin
6-MMP: 6-methyl-mercaptopurine
NSAID: nonsteroidal anti-inflammatory drug
PPAR-γ: peroxisome proliferator-activated receptor gamma
TGFR: transforming growth factor
T H: T helper (lymphocyte)
TNF-α: tumor necrosis factor alpha
TPMT: thiopurine methyltransferase
XO: xanthine oxidase
Figure 51–1  Proposed pathogenesis of IBD and target sites for pharmacological intervention. Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the epithelial barrier is impaired, bacterial antigens can gain access to APCs such as dendritic cells in the lamina propria. These cells then present the antigen(s) to CD4+ lymphocytes and also secrete cytokines such as IL-12 and IL-18, thereby inducing the differentiation of TH1 cells in Crohn disease (or, under the control of IL-4, TH2 cells in ulcerative colitis). The balance of pro-inflammatory and anti-inflammatory events is also governed by regulatory TH17 and TReg cells, both of which serve to limit immune and inflammatory responses in the GI tract. TGF-β and IL-6 are important cytokines that drive the expansion of the regulatory T-cell subsets. TH1 cells produce a characteristic array of cytokines, including IFN-γ and TNF-α, which in turn activate macrophages. Macrophages positively regulate TH1 cells by secreting additional cytokines, including IFN-γ and TNF-α. Recruitment of a variety of leukocytes is mediated by activation of resident immune cells, including neutrophils. Cell adhesion molecules such as integrins are important in the infiltration of leukocytes, and novel biological therapeutic strategies aimed at blocking leukocyte recruitment are effective at reducing inflammation. General immunosuppressants (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine) affect multiple sites of inflammation. More site-specific interventions involve intestinal bacteria (antibiotics, prebiotics, and probiotics) and therapy directed at TNF-α, IL-12/23, or integrins.

Moderate-to-severe IBD. Patients with IBD segregate into three general groups with respect to their response to glucocorticoids:

- **Glucocorticoid-responsive patients** improve clinically within 1–2 weeks and remain in remission as the steroids are tapered and then discontinued.
- **Glucocorticoid-dependent patients** respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered or discontinued.
- **Glucocorticoid-unresponsive or “steroid-resistant” patients** do not improve even with prolonged high-dose steroids.

Glucocorticoids induce a reduction in the inflammatory response and symptomatic remission in most patients with Crohn disease, with improvement generally occurring within 5 days of initiating treatment; however, some patients require treatment for several weeks before remission occurs. Glucocorticoids sometimes are used for prolonged periods to control symptoms in corticosteroid-dependent patients, as these patients will often experience a recurrence of their disease as the glucocorticoid is withdrawn. A proportion of patients with IBD are steroid resistant, and the failure to respond to steroids with prolonged remission (i.e., a disease relapse) should prompt consideration of adjunctive and alternative therapies, including immunosuppressive agents and biological therapies (Manz et al., 2012). Glucocorticoids are not a safe or practical means to maintain remission in either ulcerative colitis or Crohn disease due to the high rate of adverse events associated with their prolonged use. The most commonly used glucocorticoid in Crohn disease is **prednisone**, given orally or intravenously. For more severe cases, glucocorticoids such as **methylprednisolone** or **hydrocortisone** are given intravenously.
Figure 51–2  Sulfasalazine and related agents. The red N atoms indicate the diazo linkage that is cleaved to generate the active moiety.

The enteric-release form of the synthetic steroid, budesonide, is used for ileocecal Crohn disease. Its putative action is the delivery of therapeutic quantities of steroid to a specific portion of inflamed gut while minimizing systemic side effects, owing to its local release and extensive first-pass hepatic metabolism to inactive derivatives such that systemic levels remain low. Generally, however, oral budesonide is considered less effective than conventional glucocorticoids. Budesonide is FDA-approved for use in the short-term maintenance of remission (up to 3 months), although recent studies have suggested it is not more effective than placebo for this indication (Kuenzig et al., 2014).

Glucocorticoid enemas are useful mainly in patients whose disease is limited to the rectum and left colon. Betamethasone and budesonide are available as retention enemas. Patients with distal disease usually respond within 3–7 days. Absorption, although less than with oral preparations, is still substantial (up to 50%–75%). Hydrocortisone also can be given once or twice daily as a 10% foam suspension that delivers 80 mg per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining enemas.

ADME
Prednisone is the most commonly administered glucocorticoid and is used for the induction of remission of moderate-to-severe Crohn disease in patients who do not respond to 5-ASA drugs (Benchimol et al., 2008).

Figure 51–3  Metabolic fates of the different oral formulations of 5-ASA. Chemical structures are in Figure 51–2. 4-ABA, 4-aminobenzoyl-β-alanine.

It is sometimes given as a first-line therapeutic to induce remission. Prednisone is most often administered orally but can be administered intravenously when patients present with severe, acute flares of disease. Initial doses in IBD are 40–60 mg of prednisone or equivalent per day; higher doses are generally no more effective. Most patients respond within 10–14 days, at which point the dose is reduced by 5 mg per week (tapered) over several weeks to months. Prednisone is absorbed at a rate of 50%–90%; 65%–90% of the absorbed drug is protein bound in the serum. It is metabolized to the active compound, prednisolone, in the liver. The $t_{1/2}$ for prednisone is about 3.5 h, with metabolized drug excreted in the urine. Because of the complex nature of the mechanism of action of glucocorticoids, numerous drug interactions have been reported. Budesonide for the treatment of IBD is administered orally at a dose of 9 mg/d for up to 8 weeks (Kane et al., 2002). There is usually no therapeutic benefit of continuing treatment beyond 3 months. The bioavailability of orally administered budesonide is limited (9%–21%) by its high first-pass metabolism. The time to peak serum concentration is 7–19 h when given in capsule form. The $t_{1/2}$ is about 2–3.6 h. Excretion of metabolites is renal (60%) and fecal.

Adverse Effects
The significant adverse events associated with conventional glucocorticoids such as prednisone limit their long-term use. These are numerous, but among the more common are skin and soft tissue manifestations, including skin thinning and the development of Cushingoid features (weight redistribution and weight gain). Other side effects include cardiovascular events and psychiatric and cognitive effects. Conventional glucocorticoids can suppress the HPA axis, which can result in adrenal insufficiency when the drug is withdrawn abruptly. This effect necessitates the tapering of dose rather than quick withdrawal of the drug. The mechanisms underlying these and other adverse effects of conventional glucocorticoids are detailed in Chapter 46. Budesonide has a similar profile of adverse events, but with lower incidence due to its extensive first-pass hepatic metabolism.

Immunomodulatory Agents
Several drugs developed for cancer chemotherapy or as immunosuppressive agents in organ transplants are also used for treatment of IBD.

Figure 51–4  Sites of release of mesalamine (5-ASA) in the GI tract from different oral formulations.
Clinical experience has defined specific roles for each of these agents as mainstays in the pharmacotherapy of IBD. However, their potential for serious adverse effects mandates a careful assessment of risks and benefits in each patient.

**Thiopurine Derivatives**

The cytoxic thiopurine derivatives mercaptopurine and azathioprine (see Chapters 35 and 66) are used off label to treat patients with severe IBD or those who are steroid resistant or steroid dependent (Coskun et al., 2016). These thiopurines impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: Azathioprine is converted to 6-mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides, the putative active moieties (Figure 51–5).

**Therapeutic Uses.** These drugs are generally used interchangeably with appropriate dose adjustments, typically azathioprine (1.5–2.5 mg/kg) or mercaptopurine (1.5–2.0 mg/kg) in both Crohn disease and ulcerative colitis as an adjunct to glucocorticoids and biologics (Nielsen et al., 2001). They help maintain remission in both diseases; they also may prevent or delay recurrence of Crohn disease after surgical resection. Finally, they are used to treat fistulas in Crohn disease. The clinical response to azathioprine or mercaptopurine may take weeks to months, so that other drugs with a more rapid onset of action (e.g., mesalamine, glucocorticoids, or biologics) are preferred in the acute setting.

In general, physicians who treat IBD believe that the long-term risks of azathioprine-mercaptopurine are lower than those of steroids. Thus, these purines are used in glucocorticoid-unresponsive or glucocorticoid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. In addition, patients who have not responded adequately to mesalamine but are not acutely ill may benefit by conversion from glucocorticoids to immunomodulatory drugs. Immunomodulators therefore may be viewed as steroid-sparing agents.

**ADME.** Favorable responses to azathioprine-mercaptopurine are seen in up to two-thirds of patients. Mercaptopurine has three metabolic fates (Figure 51–5):

- conversion by XO to 6-thiouric acid;
- metabolism by TPMT to 6-MMP; and
- conversion by HPRT to 6-thioguanine nucleotides and other metabolites.

The relative activities of these different pathways may explain, in part, individual variations in efficacy and adverse effects.

The plasma t½ of mercaptopurine is limited by its relatively rapid (i.e., within 1–2 h) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug’s fate. Approximately 80% of the U.S. population has what is considered “normal” metabolism, whereas 1 in 300 individuals have minimal TPMT activity. In the latter setting, mercaptopurine metabolism is shifted away from 6-MMP and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, about 10% of the population are rapid metabolizers. In these individuals, mercaptopurine is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Pharmacogenetic typing can guide therapy (see Chapter 7).

Xanthine oxidase in the small intestine and liver converts mercaptopurine to thiouric acid, which has no therapeutic activity. Inhibition of XO by allopurinol diverts mercaptopurine to more active metabolites, such as 6-thioguanine, increasing both immunomodulatory and potential toxic effects. Thus, patients on mercaptopurine should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

**Adverse Effects.** Adverse effects of azathioprine-mercaptopurine can be either idiosyncratic or dose related. Adverse effects occur at any time after initiation of treatment and can affect up to 10% of patients. One of the most serious idiosyncratic reactions is pancreatitis, which affects about 5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally; nausea and vomiting are somewhat more frequent. The major dose-related adverse effect is bone marrow suppression, and blood counts should be monitored closely when therapy is initiated and at less-frequent intervals during maintenance therapy. Elevations in liver function tests also may be dose related. The serious adverse effect of cholestatic hepatitis is relatively rare. Thiopurines given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin lymphoma.

**Methotrexate**

Methotrexate is a folic acid analogue that inhibits dihydrofolate reductase, thereby blocking DNA synthesis and causing cell death (Coskun et al., 2016). The anti-inflammatory effects of methotrexate may involve mechanisms in addition to inhibition of dihydrofolate reductase. These include inhibition of purine metabolism, inhibition of T-cell activation and production of cytokines and intercellular adhesion molecules, and inhibition of IL-1β receptor binding.

**Therapeutic Uses.** Methotrexate is reserved for patients whose IBD is either steroid resistant or steroid dependent. In Crohn disease, it is used for maintenance of remission and as an adjunct to biologics to boost efficacy and reduce formation of antidrug antibodies (Patel et al., 2014). Methotrexate (15–25 mg/week) is generally administered parenterally. The choice of parental administration reflects the unpredictable intestinal absorption at higher doses of methotrexate and in the presence of intestinal disease. A dose of 25 mg weekly is often used for induction of the remission of the inflammatory response, with 15 mg given once weekly for maintenance of remission. Methotrexate is sometimes used in combination with anti–TNF-α antibody therapy (see discussion that follows).

**ADME.** Methotrexate is administered intramuscularly or subcutaneously for induction and maintenance of remission of Crohn disease. After administration, approximately 50% is bound to serum proteins. Methotrexate can cross the blood-brain barrier but occurs at much lower levels in cerebrospinal fluid than in serum. It has a t½ of about 3–10 h at doses used for the treatment of Crohn disease (see Appendix II). Approximately 90% of administered methotrexate appears unaltered in the urine, likely as a result of active tubular secretion.

**Adverse Effects.** Drugs that inhibit renal excretion of MTX may increase treatment-related toxicity. These include NSAIDs, phenytoin, ciprofloxacin, penicillin-type drugs, probenecid, amiodarone, and proton pump inhibitors. Methotrexate, at the doses used for the treatment of Crohn disease, is generally well tolerated. When toxicity occurs, it manifests as nausea, loose stool, stomatitis, punctate cutaneous erosion, CNS symptoms (including headache, fatigue, and impaired ability to concentrate),...
Cyclosporine
Cyclosporine is an inhibitor of calcineurin and a potent immunomodulator used most frequently after organ transplantation (see Chapter 35). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication.

Therapeutic Uses. Between 50% and 80% of these severely ill patients with IBD improve significantly (generally within 7 days) in response to intravenous cyclosporine (2–4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of cyclosporine levels is necessary to maintain a therapeutic level between 300 and 400 ng/mL of whole blood. Oral cyclosporine is less effective as maintenance therapy in Crohn disease, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with formulations of cyclosporine that have increased oral bioavailability may be more effective. Cyclosporine can be used to treat fistulous complications of Crohn disease. A significant rapid response to intravenous cyclosporine has been observed; however, frequent relapses accompany oral cyclosporine therapy, and other medical strategies are required to maintain fistula closure. Thus, calcineurin inhibitors generally are used to treat specific problems over the short-term while providing a bridge to longer-term therapy.

ADME. Cyclosporine given orally is erratic and incompletely absorbed by the intestine. Following absorption, 90%–98% is bound to serum lipoproteins. Depending on the formulation, the t₁/₂ is biphasic, with the terminal phase being about 9–18 h.

Adverse Effects. The significant adverse effects associated with the use of cyclosporine limit its use to specific types of severe IBD. These side effects most often include increased susceptibility to infections, renal insufficiency, hypertension, seizures, and peripheral neuropathy. Significant drug interactions have been reported. Other immunosuppressants that are being evaluated in IBD include the calcineurin inhibitor tacrolimus (FK506) and the inhibitors of inosine monophosphate dehydrogenase, mycophenolate mofetil and mycophenolate, to which lymphocytes are especially susceptible (see Chapter 35).

Biological Therapies for IBD
Anti–TNF-α Monoclonal Antibodies
Infliximab, adalimumab, and certolizumab pegol are monoclonal immunoglobulins that have been developed for the treatment of chronic inflammatory diseases. Infliximab is a chimeric antibody (25% mouse, 75% human), whereas adalimumab is a fully humanized antibody. Certolizumab pegol is a humanized fragment antigen binding that is “pegylated” (i.e., bound to a polyethylene glycol polymer to increase serum half-life of the parent compound). These drugs bind to and neutralize both soluble and membrane-bound TNF-α, one of the principal cytokines mediating the T₄⁺,1 immune response characteristic of Crohn disease (see Figure 51–1), thereby preventing its binding to p55 and p75 receptors. Chapters 34 and 35 present more detailed and mechanistic view of Ab production and the use of Abs to regulate immune function.

Therapeutic Uses and ADME—Crohn Disease. Monoclonal anti–TNF-α antibodies are used for moderate-to-severe Crohn disease, including fistulizing disease that is resistant to other therapies (Peyrin-Biroulet et al., 2008). The antibody preparations are used for both the induction and the maintenance of remission in adults and children. Anti–TNF-α antibodies used in the treatment of Crohn disease are administered parenterally. Infliximab is given intravenously at an initial dose of 5 mg/kg, with subsequent doses of 5 mg/kg at weeks 2 and 6, followed by maintenance doses of 5 mg/kg every 8 weeks. The t₁/₂ is about 8–10 days, although the clearance rate increases in patients who develop anti-infliximab antibodies. Adalimumab is given subcutaneously at an initial dose of 160 mg, with subsequent doses of 80 mg at week 2 and maintenance doses of 40 mg every second week starting on week 4. Bioavailability following a 40-mg dose is about 64%; the t₁/₂ is about 2 weeks.Certolizumab pegol is given at an induction dose of 400 mg subcutaneously at weeks 0, 2, and 4, and then every 4 weeks for maintenance of response. Bioavailability when given subcutaneously is about 80%; the t₁/₂ is about 2 weeks. The clearance of monoclonal anti–TNF-α antibodies is not well understood but is likely due to proteolytic degradation. The polyethylene glycol moiety of certolizumab pegol is cleared by urinary excretion.

Adverse Effects. Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion. Antibodies to infliximab can decrease its clinical efficacy (Lichtenstein, 2013). Strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy but may increase the chance of infection. Because adalimumab and certolizumab are humanized antibodies, there is less chance for the development of an immune response against them. Infliximab therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or development of opportunistic infections with subsequent dissemination. The FDA recommends that candidates for infliximab therapy be tested for latent tuberculosis with purified protein derivative; patients testing positive should be treated prophylactically with isoniazid. Infliximab is contraindicated in patients with severe congestive heart failure. There is concern about a possible increased incidence of non-Hodgkin lymphoma, but a causal role has not been established.

Although infliximab was designed specifically to target TNF-α, it may have more complex actions. Infliximab binds membrane-bound TNF-α and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, infliximab may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma t₁/₂ of 8–10 days, may explain the prolonged clinical effects of infliximab. Infliximab (5 mg/kg infused IV at intervals of every 6–8 weeks) decreases the frequency of acute flares in approximately two-thirds of patients with moderate-to-severe Crohn disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn disease. Emerging evidence also supports its efficacy in maintaining remission and in preventing recurrence of fistulas. The combination of infliximab and azathioprine is more effective than infliximab alone in induction of remission and mucosal healing in steroid-resistant patients.

Other Monoclonal Antibodies for the Treatment of Crohn Disease
Vedolizumab is a humanized, monoclonal antibody that binds to and inhibits the α₄-integrin subunit and therefore blocks binding of α₄β₇ and α₉β₇ on lymphocytes to addressin (also known as mucosal vascular addressin cell adhesion molecule, MADCAM 1) on venular endothelial cells, thus preventing lymphocyte recruitment to the intestinal mucosa (Jovani and Danese, 2013). It is approved for use in the treatment of moderate-to-severe Crohn disease and ulcerative colitis. Vedolizumab is generally given at a dose of 300 mg at 0, 2, and 6 weeks, with maintenance doses given every 8 weeks thereafter. The main side effects are headache, hypersensitivity reactions, arthralgia, nasopharyngitis, and fatigue. Anti–TNF-α drugs may enhance the adverse effects of vedolizumab.

Ustekinumab is a monoclonal antibody that targets the p40 subunit common to the pro-inflammatory cytokines IL-12 and IL-23, thus preventing activation of IL-12p40 and IL-23 receptors on lymphocytes (Teng et al., 2015). Originally developed for the treatment of psoriasis, it shows efficacy in the induction and maintenance of remission in Crohn disease. Trials indicate effective induction and maintenance of remission at a dose of 6 mg/kg (Khanna et al., 2015). During the initial trials of ustekinumab for Crohn disease, side effects included headache, arthralgia, infection, nausea, and nasopharyngitis.

Therapeutic Uses and ADME—Ulcerative Colitis. Unlike Crohn disease, ulcerative colitis can be cured with surgery (colectomy). Thus, the cost and potential adverse events associated with monoclonal antibody
therapy need to be balanced with the effectiveness of the drug at preventing the need for colonic resection. Biologics are well established in their use in ulcerative colitis, particularly in those patients for whom primary therapy with glucocorticoids, 5-ASA, or immunomodulators has failed. Infliximab, adalimumab, and golimumab have become mainstays in the treatment of ulcerative colitis, and vedolizumab is also now available. Large controlled clinical trials have demonstrated that anti–TNF-α agents significantly reduce the severity of the inflammation that characterizes ulcerative colitis. Similarly, vedolizumab is now indicated and approved for the treatment of moderate-to-severe ulcerative colitis. The administration, dosing, metabolism, and adverse events are similar for the use of these drugs in ulcerative colitis and Crohn disease.

Manipulating the Intestinal Microbiome to Treat IBD

Antibiotics and Probiotics
A balance normally exists in the GI tract among the mucosal epithelium, the normal gut flora, and the immune response (Biten et al., 2016; Schreiner et al., 2015). Dysbiosis of the intestinal microbiome is now considered a key factor in the development of IBD (Dalal and Chang, 2014). Thus, certain bacterial strains may be either pro- (e.g., Bacteroides) or anti-inflammatory (e.g., Lactobacillus), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used most prominently in Crohn disease.

Antibiotics can be used as:
• adjunctive treatment along with other medications for active IBD in severe cases where there is concern about coexisting sepsis
• treatment of perforating or fistulizing complications of Crohn disease
• prophylaxis for recurrence in postoperative Crohn disease

Metronidazole, ciprofloxacin, amoxicillin-clavulanate, and piperacillin-tazobactam are the antibiotics used most frequently. Crohn disease–related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small-bowel bacterial overgrowth secondary to partial small-bowel obstruction, secondary infections with organisms such as Clostridium difficile, and postoperative complications.

More recently, probiotics have been used to treat specific clinical situations in IBD. Probiotics are mixtures of putatively beneficial lophylized bacteria given orally. Several studies have provided evidence for beneficial effects of probiotics in ulcerative colitis and pouchitis (Sokol, 2014). However, the utility of probiotics as a primary therapy for IBD remains unclear.

Fecal Transplant as Therapy in IBD
The recognition that the etiology of IBD involves dysbiosis of the intestinal microbiome has raised interest in methods to reestablish normal microbiota in patients. Fecal transplant involves the instillation of a preparation of feces from a healthy donor into the colon, either by enema or during colonoscopy. This has proven to be an effective therapy for antibiotic-resistant C. difficile infection. Several clinical trials have assessed the efficacy of fecal transplant in Crohn disease and ulcerative colitis, with varying results (Hansen and Sartor, 2015).

Supportive Therapy in IBD
Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. Oral iron, folate, and vitamin B₁₂ should be administered as indicated. Loperamide or diphenoxylate (see Chapter 50) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease in selected circumstances; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. Cholestyramine can be used to treat bile salt–induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (dicyclomine hydrochloride, etc.; Chapter 10) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected.

Pediatric IBD
Children and adolescents remain the fastest-growing group of patients with IBD. On average, children present with more severe disease than do adults. In addition, while many children present with the classical symptoms of IBD, approximately 22% of children present with additional symptoms, such as growth failure, perianal disease, or other extraintestinal manifestations as the primary symptom, thus complicating diagnosis.

The drugs used for treating pediatric IBD are the same as those used for the treatment of these diseases in adults. Exclusive enteral nutrition is an effective alternative to 5-ASA compounds, glucocorticoids, immunosuppressants, and biologics. Indeed, 8–12 weeks of liquid formula as the sole source of calories is as effective as glucocorticoids in relieving symptoms and has the advantage of supporting growth (Rosen et al., 2015). In terms of drug therapy, a child’s immunization status should be considered before commencing immunosuppressive therapy (glucocorticoids, azathioprine–methotrexate, anti–TNF-α drugs). Children should be tested for latent tuberculosis, particularly prior to treatment with anti–TNF-α drugs. During treatment, children may receive inactivated vaccines, but it is not recommended that they be given live vaccines.

Antibiotics have recently been shown to have some utility in treating mild-to-moderate pediatric Crohn disease. In particular, ciprofloxacin, metronidazole, and rifaximin were demonstrably effective in small clinical trials (Serban, 2015). Their role in the treatment of ulcerative colitis has yet to be established.

Therapy of IBD During Pregnancy
Inflammatory bowel disease is a chronic disease that affects women in their reproductive years. In general, decreased disease activity improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease. The use of medical therapies to treat IBD during pregnancy and lactation has been reviewed (Nielsen et al., 2014), although studies that thoroughly investigated the use of medications to treat IBD in pregnancy are limited (Damas et al., 2015). Mesalamine and glucocorticoids are FDA category B drugs (see Appendix I) that are used frequently in pregnancy and generally are considered safe, whereas methotrexate is absolutely contraindicated in pregnant patients. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives. Anti–TNF-α drugs, particularly infliximab and adalimumab, have been assessed for their safety for use during pregnancy and have been found to have low risk for adverse events (Khan et al., 2014).

General Principles of Antimicrobial Therapy
Tawanda Gumbo

Antimicrobial Chemotherapy: Classes and Actions

The germ theory of disease, based on the work of Louis Pasteur and Robert Koch, was a revolution in the human understanding of nature that linked specific microorganisms to specific diseases. The germ theory developed considerably in the 20th century, with identification and characterization of many microbial pathogens and their pathogenic mechanisms and the introduction of antimicrobial drugs. With the use of these drugs came issues of appropriate regimens, drug resistance, drug interactions, and toxicity.

This chapter reviews the general classes of antimicrobial drugs, their mechanisms of action, mechanisms of resistance, and patterns of kill by different classes of the drugs. Chapters 53 through 64 present the pharmacological properties and uses of individual classes of antimicrobials.

Microorganisms of medical importance fall into four categories: bacteria, viruses, fungi, and parasites. The first broad classification of antibiotics follows this classification closely, so that we have antibacterial, antiviral, antifungal, and antiparasitic agents. However, there are many antibiotics that work against more than one category of microbes, especially those that target evolutionarily conserved pathways. Within each of these major categories, drugs are further categorized by their biochemical properties.

Antimicrobial molecules should be viewed as ligands whose receptors are microbial proteins. The term pharmacophore, introduced by Ehrlich, defines that active chemical moiety of the drug that binds to the microbial receptor. The microbial proteins targeted by the antibiotic are essential components of biochemical reactions in the microbes, and interference with these physiological pathways kills the microorganisms. The biochemical processes commonly inhibited include cell wall synthesis in bacteria and fungi, cell membrane synthesis, synthesis of 30S and 50S ribosomal subunits, nucleic acid metabolism, function of topoisomerases, viral proteases, viral integrases, viral envelope entry/fusion proteins, folate synthesis in parasites, and parasitic chemical detoxification processes. Recently, antisense antibiotics have been developed; these work by inhibiting gene expression in bacteria in a sequence-specific manner. Furthermore, interferon-based products work by inducing specific antiviral activities of the infected human cells.

Classification of an antibiotic is based on the following:

- class and spectrum of microorganisms it kills
- biochemical pathway it interferes with
- chemical structure of its pharmacophore

Because antimicrobial agents are ligands that bind to their targets to produce effects, the relationship between drug concentration and effect on a population of organisms is modeled using the standard Hill-type curve for receptor and agonist (Chapters 2 and 3), characterized by three parameters:

- $IC_{50}$ (also termed $EC_{50}$), the inhibitory concentration that is 50% effective, a measure of the antimicrobial agent's potency
- $E_{max}$, a measure of the maximal effect
- $H$, the slope of the curve, or Hill factor

In antimicrobial therapy, the relationship is often expressed as an inhibitory sigmoid $E_{max}$ model (Figure 52–1), to take into account the control bacterial population without treatment ($E_{max}$) as a fourth parameter (Equation 52–1 and Figure 52–1), where $E$ is effect as measured by microbial burden.

$$E = E_{max} - E_{max} \times \left(\frac{IC}{[IC]^{H} + [IC]^{H+1}}\right)$$  (Equation 52–1)

Definitive Therapy With Known Pathogen
Posttreatment Suppressive Therapy

Mechanisms of Resistance to Antimicrobial Agents

- Resistance Due to Reduced Entry of Drug Into Pathogen
- Resistance Due to Drug Efflux
- Resistance Due to Destruction of Antibiotic
- Resistance Due to Altered Target Structure
- Incorporation of Drug
- Resistance Due to Enhanced Excision of Incorporated Drug
- Heteroresistance and Viral Quasi-Species

Evolutionary Basis of Resistance Emergence

- Development of Resistance via Mutation Selection
- Hypermutable Phenotypes
- Resistance by External Acquisition of Genetic Elements
- Horizontal Gene Transfer

Basis for Selection of Dose and Dosage Schedule

- Prophylactic Therapy
- Empirical Therapy in the Symptomatic Patient

Types and Goals of Antimicrobial Therapy

- Definitive Therapy With Known Pathogen
- Posttreatment Suppressive Therapy

The pharmacokinetic basis of antimicrobial therapy

- Penetration of Antimicrobial Agents Into Anatomic Compartments
- Pharmacokinetic Compartments
- Population Pharmacokinetics and Variability in Drug Response

Impact of Susceptibility Testing on Success of Antimicrobial Agents

- Bacteria
- Fungi
- Viruses
- Parasites

Classification of an antibiotic is based on the following:

- class and spectrum of microorganisms it kills
- biochemical pathway it interferes with
- chemical structure of its pharmacophore

Because antimicrobial agents are ligands that bind to their targets to produce effects, the relationship between drug concentration and effect on a population of organisms is modeled using the standard Hill-type curve for receptor and agonist (Chapters 2 and 3), characterized by three parameters:

- $IC_{50}$ (also termed $EC_{50}$), the inhibitory concentration that is 50% effective, a measure of the antimicrobial agent's potency
- $E_{max}$, a measure of the maximal effect
- $H$, the slope of the curve, or Hill factor

In antimicrobial therapy, the relationship is often expressed as an inhibitory sigmoid $E_{max}$ model (Figure 52–1), to take into account the control bacterial population without treatment ($E_{max}$) as a fourth parameter (Equation 52–1 and Figure 52–1), where $E$ is effect as measured by microbial burden.

$$E = E_{max} - E_{max} \times \left(\frac{IC}{[IC]^{H} + [IC]^{H+1}}\right)$$  (Equation 52–1)
Examples of antimicrobial agents that are polar at physiological pH generally penetrate poorly; some, such as penicillin G, are actively transported out of the CSF and achieve CSF concentrations of only 0.5%–5% of the C\text{p}\text{-time} curve. How- ever, the integrity of the blood-brain barrier is diminished during active infections; tight junctions in cerebral capillaries open, leading to a marked increase in the penetration of even polar drugs. As the infection is eradicated and the inflammatory reaction subsides, penetration diminishes to normal. Because this may occur while viable microorganisms persist in the CSF, drug dosage should not be reduced as the patient improves.

**Eye**

Drug penetration into the eye is especially pertinent in the treatment of endophthalmitis and infections of the retina. There is generally poor penetration of drug from plasma to this compartment, so that the standard therapy is direct instillation of antibiotics into the ocular cavity (see Chapter 69). In patients with pulmonary infections such as pneumonia, drugs must penetrate into the ELF, where the pathogens are found (Kiem and Schentag, 2008).

**Pericardium**

Drug penetration into the pericardium is governed by physical barriers and also likely by some form of active transport. In patients treated for tuberculous pericarditis with the regimen of isoniazid, rifampin, pyrazinamide, and ethambutol, simultaneous blood and pericardial fluid concentrations were measured over 24 h (Shenje et al., 2015). Rifampin concentrations in pericardial fluid were only 20% those in plasma due to poor penetration as well as active clearance, while ethambutol C\text{peak} was 55% due to poor penetration. On the other hand, isoniazid and pyrazinamide concentrations in pericardial fluid and blood were equivalent. Do not assume that different drugs penetrate equally to the compartment of concern.
Biofilms

Compartments requiring special drug penetration are endocardial vegetations and the biofilm formed by bacteria and fungi on prosthetic devices such as artificial heart valves, long-dwelling intravascular catheters, artificial hips, and devices for internal fixation of bone fractures. Bacterial and fungal biofilms are colonies of slowly growing cells enclosed within an exopolymer matrix. The exopolysaccharide is negatively charged and can bind positively charged antibiotics and restrict their access to the intended target. To be effective against infections in these compartments, antibiotics have to be able to penetrate the biofilm and endothelial barriers (Sun et al., 2013).

Pharmacokinetic Compartments

Once an antibiotic has penetrated to the site of infection, it may be subjected to processes of elimination and distribution that differ from those in the blood. Sites where the concentration-time profiles differ from each other are considered separate pharmacokinetic compartments; thus, the human body is viewed as multicompartamental. The concentration of antibiotic within each compartment is assumed to be homogeneous. If two compartments have similar concentration profiles, then they may be considered a single compartment. Antibiotic concentrations can be analyzed using any number of such compartments, with the best number of compartments chosen based on the least number of compartments that can adequately explain the findings. The model is also defined as open or not open; an open model is one in which the drug is eliminated out of the body from the compartment (e.g., kidneys). The kinetic order of the process must also be specified (Chapter 2): A first-order process is directly correlated to concentration of drug D, or [D]1, as opposed to zero order, which is independent of [D] and reflects a process that is saturated at ambient levels of D (such as the elimination of ethanol; Chapter 23).

Consider a patient with pneumonia, with the pathogen in the lung ELF. The patient ingests an antibiotic that is absorbed via the GI tract (g) into blood or the central compartment (compartment 1) as a first-order input. In this process, the transfer constant from the GI tract to central compartment is termed the absorption constant and is designated . The antibiotic in the central compartment is then delivered to the lungs, where it penetrates into the ELF (compartment 2). However, it also penetrates into other tissues of the body peripheral to the site of infection, termed the peripheral compartment (compartment 3). Thus, we have four compartments (including g, a specific compartment, the GI tract, from the set of initial absorption compartments in Figure 52–2), each with its own concentration-time profile. The penetration of drug from compartment 1 to 2 is based on the penetration factors discussed previously and is defined by the transfer constant . However, the drug also redistributes from compartment 2 back to 1, defined by transfer constant . A similar process between the blood and peripheral tissues leads to transfer constants and . The drug may also be lost from the body (i.e., open system) via the lungs and other peripheral tissues (e.g., kidneys or liver) at a rate proportional to the concentration.

Antibiotic concentrations within each compartment change with time (the changes are described using standard differential equations). If X is the amount of antibiotic in a compartment, SCL the drug clearance, and V the volume of the central compartment, then equations for absorption compartment (Equation 52–2), central compartment (Equation 52–3), site of infection or compartment 2 (Equation 52–4), and peripheral compartment (Equation 52–5) are as follows:

\[ \frac{dX}{dt} = -K_c \cdot X_t \]  
\[ \frac{dX_c}{dt} = K_{12} \cdot X_t - \left[ (SCL/V) + K_{13} \right] \cdot X_c + K_{23} \cdot X_s + K_{31} \cdot X_p \]  
\[ \frac{dX_s}{dt} = K_{21} \cdot X_t - K_{13} \cdot X_s \]  
\[ \frac{dX_p}{dt} = K_{31} \cdot X_s - K_{32} \cdot X_p \]

Such models have been used in conjunction with population pharmacokinetics to describe and model a plethora of antimicrobials used to treat bacteria, fungi, viruses, and parasites (Hope et al., 2007; Tarning et al., 2008; Wilkins et al., 2008). Semimechanistic models have been applied to relate pathogen response to drug concentrations within these pharmacokinetic compartments in preclinical disease models and in patients (Gumbo et al., 2006; Jumbe et al., 2003; Talal et al., 2006). These models can be made more complex and more predictive by adding parameters describing the effect of inoculum, delay in microbial effect, or splitting the drug-resistant population to smaller subpopulations based on a molecular mechanism of resistance (Bulitta et al., 2009).

Population Pharmacokinetics and Variability in Drug Response

When multiple patients are treated with the same dose of a drug, each patient will achieve unique pharmacokinetic parameters. This is termed between-patient variability. Even when the same dose is administered to the same patient on two separate occasions, the patient may achieve a different concentration-time profile of the drug between the two occasions.
This is termed interoccasion or within-patient variability. The variability is reflected at the level of the compartmental pharmacokinetic parameters in Equations 52–2 to 52–5, such as $k$, $k_{in}$, $SCL$, $V$, and so on. Even when a recommended dose is administered, the drug may fail to reach a therapeutic concentration in some patients, purely because of the between-patient variability.

An important example of the consequences of between-patient variability involves antituberculosis drugs: In patients who are adherent to therapy, subtherapeutic concentrations of isoniazid, rifampin, pyrazinamide, and ethambutol account for more than 90% of therapy failure, slower sterilizing effect, and acquired drug resistance (Chigutsa et al., 2015; Pasipanodya et al., 2013). The same has been seen with antileishmania drugs and antifungal agents (Andes et al., 2011; Dorlo et al., 2014). In other patients, the drug may reach high and toxic concentrations because of the between-patient variability. Such variability could be due to genetic variability, weight, height, age, and comorbid conditions such as renal and liver dysfunction. An important driver of variability is the widespread problem of overweight and obesity, which increases the clearance and can alter the volume of distribution of many antibiotics. This emerging problem is prompting changes in dosing strategies.

Drug interactions are another important source of variability with potentially dangerous consequences. These interactions usually occur when one drug inhibits or induces uptake or clearance mechanisms affecting another drug (see Chapters 5 and 6).

The common practice of using an “average” value of data, or “naive pooling,” has implications of smoothing out data and failing to recognize subgroups of patients at risk for therapeutic failure or increased toxicity of antibiotic. Knowledge of covariates associated with pharmacokinetic variability leads to better dose adjustments, switching therapy from one antibiotic to another, or changing concomitant medications.

### Impact of Susceptibility Testing on Success of Antimicrobial Agents

The microbiology laboratory plays a central role in the decision to choose a particular antimicrobial agent over others. First, identification and isolation of the culprit organism takes place when the patients’ specimens are sent to the microbiology laboratory. Once the microbial species causing the disease has been identified, a rational choice of the class of antibiotics likely to work in the patient can be made. The microbiology laboratory then plays a second role, which is to perform susceptibility testing.

Millions of individuals across the globe become infected by many different isolates of the same species of pathogen. Evolutionary processes cause each isolate to be slightly different from the next, so that each may have a unique susceptibility to antimicrobial agents. As the microorganisms divide within the patient, they may undergo further evolution between the time of infection and the time of diagnosis. Therefore, one observes a distribution of concentrations of antimicrobial agents that can kill the pathogens. Often, this distribution is Gaussian, with a skew that depends on where the patient lives. Such factors will affect the shape of the inhibitory sigmoid $E_{\text{max}}$ model curve described by Equation 52–1.

With changes in susceptibility, the sigmoid $E_{\text{max}}$ curve shifts in one of two basic ways. The first is a shift to the right, an increase in $IC_{50}$ (Figure 52–3A), meaning that much higher concentrations of antimicrobials than before are now needed to show specific effect. Susceptibility tests for bacteria, fungi, parasites, and viruses have been developed to determine whether these shifts have occurred at a sufficient magnitude to warrant higher doses of drug to achieve particular effect. The change in $IC_{50}$ may become so large that it is not possible to overcome the concentration deficit by increasing the antimicrobial dose without causing toxicity to the patient. At that stage, the organism is now “resistant” to the particular antibiotic.

A second possible change in the curve is decrease in $E_{\text{max}}$ (Figure 52–3B), such that increasing the dose of the antimicrobial agent beyond a certain point will achieve no further effect; that is, changes in the microbe are such that eradication of the microbe by the particular drug can never be achieved. This occurs because the available target proteins have been reduced or the microbe has developed an alternative pathway to overcome the biochemical inhibition. For example, maraviroc is an allosteric, noncompetitive antagonist that binds to the CCR5 receptor of patient’s CD4 cells to deny HIV entry into the cell. Viral resistance occurs by a mechanism that involves HIV adapting to use of the maraviroc-bound CCR5, which results in decrease of $E_{\text{max}}$ in phenotypic susceptibility assays (Hirsch et al., 2008).

### Bacteria

For bacteria, dilution tests employ antibiotics in serially diluted concentrations on solid agar or in broth medium that contains a culture of the test microorganism. The lowest concentration of the agent that prevents visible growth after 18–24 h of incubation is known as the minimum inhibitory concentration (MIC).

Recently, nucleic acid amplification–based reactions of specific bacterial genes have been used in the clinic for rapid diagnosis of drug resistance. The genes targeted are those encoding known drug resistance proteins or processes. For example, rifampin resistance in Mycobacterium tuberculosis has been difficult to ascertain in a timely fashion: The bacteria take 2 to 3 weeks to grow in order to identify them as a cause of disease, and then a similar amount of time is needed to form some version of the broth dilution tests. Small PCR reactions at points of care can purify and concentrate a patient’s fluid sample, perform nucleic acid amplification of a target gene, identify mutations, and provide a result in less than 2 h. In other bacteria, MALDI–TOF MS is being used for identification of resistance to drugs such as vancomycin in Staphylococcus aureus and is being extended to many other compounds and bacterial species.

### Fungi

For fungi that are yeasts (i.e., Candida), susceptibility testing methods are similar to those used for bacteria. However, the definitions of MIC differ
based on drug and the type of yeast, so there are cutoff points of 50% decrease in turbidity compared to controls at 24 h, 80% at 48 h, or total clearance of the turbidity. Susceptibility tests and MICs for triazoles have been extensively shown to correlate with clinical outcomes.

Standardized tests for echinocandin antifungals and amphoterin B–based compounds are available. Susceptibility tests for molds have also been developed, especially for Aspergillus species. Different terminology from MICs is required when evaluating echinocandins against molds because the fungal burden cannot be readily measured, given that hyphae will break up into unpredictable numbers of discrete fungi when under antifungal pressure. Furthermore, echinocandins often do not completely inhibit mold growth, but instead cause damage reflected by morphological changes in hyphae. Thus, the minimum effective concentration (MEC) for echinocandins is the lowest drug concentration at which short, stubby, and highly branched hyphae are observed on microscopic examination.

**Viruses**

In HIV phenotypic assays, the patient’s HIV-RNA is extracted from plasma, and genes for targets of antiretroviral drugs such as reverse transcriptase and protease are amplified. The genes are then inserted into a standard HIV vector that lacks an alogous gene sequences to produce a recombinant virus, which is cocultivated with a drug of interest in a mammalian cell viability assay (Hanna and D’Aquilia, 2001; Petropoulos et al., 2000). Growth is compared to a standardized wild-type control virus.

Genotypic tests are now a standard part of HIV care in many parts of the world. The simplest tests measure presence of mutations associated with loss of susceptibility to a drug, that is, that the organism is “resistant” to the drug and the drug should not be used to treat that patient.

**Parasites**

Susceptibility testing for parasites, especially those that cause malaria, has been performed in the laboratory. The tests are similar to the broth tests for bacteria, fungi, and viruses. Plasmodium species in the patient’s blood are cultured ex vivo in the presence of different dilutions of antimarial drug. A sigmoid $E_{\text{max}}$ curve for effect versus drug concentration is used to identify $IC_{50}$ and $E_{\text{max}}$. These susceptibility tests are usually field tests at sentinel sites that are used to determine if there is drug resistance in a particular area. In general, susceptibility tests for parasitic infections are not standardized. These tests are primarily used in the research setting and not for individualization of therapy.

**Basis for Selection of Dose and Dosing Schedule**

Although susceptibility testing in the laboratory is central to decision making, it does not completely predict patient response. In susceptibility tests, the drug concentration is constant; by contrast, in patients the drug concentration is dynamic and ever changing. Antibiotics are prescribed at a certain schedule (e.g., three times a day) so that there is a periodicity in the fluctuations of drug at the site of infection, and the microbe is exposed to a particular shape of the concentration-time curve. Harry Eagle performed studies on penicillin and discovered that the shape of the relationship between non–protein-bound antibiotic concentration (exposure) versus microbial kill is the inhibitory sigmoid $E_{\text{max}}$ curve of Figure 52–1. Maximal kill is actually on an asymptote, so that non–protein-bound antimicrobial exposures associated with 80%–90% of $E_{\text{max}}$ are termed optimal concentrations. This exposure can often be easily identified in preclinical models and directly applied to patient populations, provided interspecies differences in protein binding and pharmacokinetic variability are taken into account.

Third, use a dosing schedule that maximizes the antimicrobial effect; recognize that optimal microbial kill by the antibiotic may be best achieved by maximizing certain shapes of the concentration–time curve.

As an example, consider an antibiotic with a serum $t_{\text{max}}$ of 3 h that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L; the antibiotic is administered with a dosing interval of 24 h (that is, a once-daily schedule). Figure 52–4A depicts the concentration–time curve of the antibiotic, with definitions of $C_{\text{emax}}$, AUC, and the fraction of the dosing interval for which the drug concentration remains above the

Similarly, in the treatment of candidemia, the rate of response is driven by the ratio dose/MIC (Rodríguez-Tudela et al., 2007). This is not a surprise because the $IC_{50}$ shifts to the right with decrease in susceptibility (Figure 52–3A).

Second, use the optimal dose of the antibiotic for the patient, that is, the dose that achieves $IC_{50}$ to $IC_{\text{max}}$ exposures at the site of infection.

Dose by itself is a poor measure of drug exposure. Rather, actual drug concentration achieved at the site of infection is the important measure. The shape of the relationship between non–protein-bound antibiotic concentration (exposure) versus microbial kill is the inhibitory sigmoid $E_{\text{max}}$ curve of Figure 52–1. Maximal kill is actually on an asymptote, so that non–protein-bound antimicrobial exposures associated with 80%–90% of $E_{\text{max}}$ are termed optimal concentrations. This exposure can often be easily identified in preclinical models and directly applied to patient populations, provided interspecies differences in protein binding and pharmacokinetic variability are taken into account.

Third, use a dosing schedule that maximizes the antimicrobial effect; recognize that optimal microbial kill by the antibiotic may be best achieved by maximizing certain shapes of the concentration–time curve.

As an example, consider an antibiotic with a serum $t_{\text{max}}$ of 3 h that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L; the antibiotic is administered with a dosing interval of 24 h (that is, a once-daily schedule). Figure 52–4A depicts the concentration–time curve of the antibiotic, with definitions of $C_{\text{emax}}$, AUC, and the fraction of the dosing interval for which the drug concentration remains above the

---

**Figure 52–4** Effect of different dose schedules on shape of the concentration–time curve. The same total dose of a drug was administrated as a single dose (panel A) and in three equal portions every 8 h (panel B). The total AUC for the fractionated dose in B is determined by adding $AUC_{0–24h}$, $AUC_{2–4}$, and $AUC_{6–24}$, which totals to the same $AUC_{0–24h}$ in A. The time that the drug concentration exceeds MIC in B is also determined by adding $T_1 > MIC$, $T_2 > MIC$, and $T_3 > MIC$, which results in a fraction greater than that for A.
Indeed, increasing Figure 52–4B 0–24 \( t \). Because the same cumulative dose has been given for the dosing interval of 24 h, the AUC\(_{\text{Cmax}}\) will be similar whether it was given once a day or three times a day. For the same pathogen, therefore, the change in dose schedule does not change the AUC\(_{\text{Cmax}}\). However, the C\(_{\text{max}}\) will decrease by a third when the total dose is split into thirds and administered more frequently (Figure 52–4B). Thus, when a dose is fractionated and administered more frequently, the C\(_{\text{max}}\)/MIC ratio decreases. In contrast, the time that the drug concentration persists above MIC (T > MIC) will increase with the more frequent dosing schedule, despite the same cumulative dose being administered. Which of the three indices (AUC/MIC, C\(_{\text{max}}\)/MIC, or T > MIC) is the most important to the outcome being assessed (i.e., microbial kill)? A common approach to the answer is to determine which of these patterns best approximates a perfect inhibitory sigmoid E\(_{\text{max}}\) curve (based on various statistical assessments of goodness of fit) in Equation 52–1.

Some classes of antimicrobial agents kill best when concentration persists above MIC for longer durations of the dosing interval. Indeed, increasing the drug concentration beyond four to six times the MIC does not increase microbial kill for such antibiotics. Two good examples are \( \beta \)-lactam antibacterials (e.g., penicillin) and the antifungal agent 5-flourocytosine (Ambrose et al., 2007; Andes and van Ogtrop, 2000). There are usually good biochemical explanations for this pattern; the clinical implication, however, is that a drug optimized by \( T > MIC \) should be dosed more frequently, or if possible should have its \( t_{1/2} \) prolonged by other drugs, so that drug concentrations persist above MIC (or E\(_{\text{max}}\)) as long as possible. Thus, the effectiveness of penicillin is enhanced when it is given as a continuous infusion. Some antibiotics, such as ceftriaxone (\( t_{1/2} = 8 \) h), have a long half-lives, such that infrequent dosing several times a day still optimizes \( T > MIC \). On the other hand, HIV protease inhibitors are often “boosted” with ritonavir. This “boosting” inhibits the metabolism of the protease inhibitors by CYPs 3A4 and 2D6, thereby prolonging time above E\(_{\text{max}}\).

Conversely, the peak concentration is what matters for other antimicrobial agents. Persistence of concentration above the MIC has less relevance for these drugs, meaning that these drugs can be dosed more intermittently. Aminoglycosides are a prime example of this class; aminoglycosides are highly effective when given once a day. These C\(_{\text{max}}\)/MIC-linked drugs can often be administered less frequently due to their long duration of PAE, with effectiveness continuing long after antibiotic concentrations decline below the MIC.

Rifampin is such a drug (Gumbo et al., 2007a). The entry of rifampin into \( M. \) tuberculosis increases with increased concentration in the bacillus microenvironment, likely because of a saturable transport process. Once inside the bacteria, the drug’s macrocyclic ring binds the \( \beta \) subunit of DNA-dependent RNA polymerase (rpoB) to form a stable drug-enzyme complex within 10 min, a process not enhanced by longer incubation of drug and enzyme and only slowly reversed. The PAE of the rifampin is long and concentration dependent (Gumbo et al., 2007a).

There is a third group of drugs for which it is the cumulative dose that matters, and for which the daily dosing schedule has no effect on efficacy. Thus, it is more ratio of the total concentration (AUC) to MIC that matters and not the time that concentration persists above a certain threshold. Antibacterial agents such as daptomycin fall into this class (Louie et al., 2001). These agents also have a good PAE. The AUC/E\(_{\text{max}}\) explains why tenofovir and emtricitabine (nucleoside analogue reverse transcriptase inhibitors) have been combined into one pill, administered once a day for the treatment of AIDS.

The shape of the concentration-time curve that optimizes resistance suppression is often different from that which optimizes microbial kill. In many instances, the drug exposure associated with resistance suppression is much higher than that for optimal kill. Ideally, this higher exposure should be achieved by each dose in patients for optimal effect, rather than the E\(_{\text{max}}\) as discussed previously. However, this is often precluded by drug toxicity at higher dosages. Second, although the relationship between kill and exposure is based on the inhibitory sigmoid E\(_{\text{max}}\) model, experimental work with preclinical models demonstrated that this model does not apply to resistance suppression (Gumbo et al., 2007b; Tam et al., 2007).

To summarize:

- The optimal dose should be designed to achieve a high probability of exceeding the E\(_{\text{max}}\) microbial PK/PD index, or an index associated with suppression of resistance, given the population pharmacokinetic variability and the MIC distribution of clinical microbe isolates.
- The dose schedule is chosen according to whether efficacy is driven by AUC/MIC (or AUC/E\(_{\text{max}}\)), C\(_{\text{max}}\)/MIC, or \( T > MIC \). Duration of therapy is then chosen based on best-available evidence.

### Types and Goals of Antimicrobial Therapy

A useful way to organize the types and goals of antimicrobial therapy is to consider where along the disease progression timetable therapy is initiated (Figure 52–5); therapy can be **prophylactic**, **preemptive**, **empirical**, **definitive**, or **suppressive**.

#### Prophylactic Therapy

Prophylaxis involves treating patients who are not yet infected or have not yet developed disease. The goal of prophylaxis is to prevent infection in some patients or to prevent development of a potentially dangerous disease in those who already have evidence of infection. The main principle behind prophylaxis is **targeted therapy**.

An important recent advance has been the understanding of the roles of the human microbiome in health. The biome is a critical defense against dangerous infections and important in uptake of vaccines. So extensive is
the putative preventive role of the microbiome that the list of conditions when it is disrupted is long, but includes common conditions such as allergies, autism, cancer, antibiotic-associated colitis, diabetes, and obesity. Thus, in routine prophylaxis there is need to preserve the native biome as much as possible. Thus, consider the following:

- Consider narrow-spectrum antibiotics targeted at the most important (potential surgical site) infectious organisms and do not target all possible bacteria.
- Limit the duration of prophylaxis to be as short as the time in which maximum contamination is expected (e.g., during incisions and the surgical procedure) and do not prolong beyond this time.
- Apply PK/PD thinking, as described previously.

Prophylaxis in Immunosuppressed Patients

Prophylaxis is used in immunosuppressed patients such as those with HIV/AIDS or are posttransplantation and on antirejection medications. The efficacy of prophylaxis in these patients is based on excellent evidence (Centers for Disease Control and Prevention et al., 2000; DHHS Panel, 2015). In these groups of patients, specific antiparasitic, antibacterial, antiviral, and antifungal therapy is administered based on the well-defined pattern of pathogens that are major causes of morbidity during immunosuppression. A risk-benefit analysis determines choice and duration of prophylaxis. Prophylaxis of opportunistic infections in patients with AIDS is started when the CD4 count falls below 200 cells/mm³, and is discontinued when the CD4 count climbs above 200 cells/mm³. In post-transplant patients, prophylaxis depends on time since the transplant procedure, which is related to intensity of use and type of immunosuppressive therapy. Prophylaxis should be discontinued in patients who are doing well at certain benchmarks, such as 1 year posttransplant. Infections for which prophylaxis is given include Pneumocystis jiroveci, Mycobacterium avium-intracellulare, Toxoplasma gondii, Candida species, Aspergillus species, Cryptococcus neoformans, and Enterovirus. In general, the prophylactic dose is lower than when the same drug is used for acute treatment.

Chemoprophylaxis for Surgical Procedures

Wound infection results when a critical number of bacteria are present in the wound at the time of closure, and chemoprophylaxis can be used to prevent wound infections after surgical procedures. Antimicrobial agents directed against the invading microorganisms may reduce the number of viable bacteria below the critical level and thus prevent infection. Because S. aureus is consistently the most common organism causing surgical site infections, programs have been developed to decolonize the patient of this organism prior to cardiac and orthopedic surgery. Approaches to decrease surgical site infections involve screening by culturing the patient’s nose and other colonization sites before surgery and decolonizing any S. aureus with intranasal mupirocin twice daily and chlorhexidine-gluconate baths daily for up to 5 days before the surgery, followed by the usual perioperative systemic antibiotics (Schweizer et al., 2015).

The systemic antibiotic used is chosen based on the pathogen most likely to contaminate the incision, which in turn depends on the site where surgery is being performed (Bratzler et al., 2013). The most common pathogens infecting incision sites after clean surgery are staphylococci, specifically S. aureus and coagulase-negative staphylococci. In clean contaminated surgery over the abdomen and pelvis, the same organisms remain important, but Enterococcus species and gram-negative rods are also common. The perioperative antimicrobial dose should be administered intravenously within 60 min prior to the surgical incision, so that concentrations are above the MIC of the organism at time of incision. The frequency of redosing during the procedure is based on the half-life of the drug in order to have adequate antibiotic concentrations above the MIC until closure of the surgical incision. This is especially important for those β-lactam antibiotics that have short half-lives; these should be redosed at intervals of two times the half-life. It is recommended that the duration of prophylaxis be shorter than 24 h postoperation and in many instances be just a single dose.

The types of surgical procedures for which systemic antibacterial prophylaxis is required has recently been expanded (Table 52–1) (Bratzler et al., 2013). The guidelines, based on consensus of opinion leaders, also suggest that the same principles for adults apply to children. However, note that the pharmacokinetics of the antibiotics may differ in children.

Prophylaxis in Patients at Risk of Infective Endocarditis

Patients at the highest risk for infective endocarditis for which prophylaxis is recommended fall into four groups (Wilson et al., 2007):

- those with a prosthetic material used for heart valve repair or replacement;
- patients having had previous infective endocarditis;
- patients with congenital heart disease such as unrepaired cyanotic heart disease, or within 6 months of repair of the heart disease with prosthetic material, or those with residual defects adjacent to prosthetic material; and
- postcardiac transplant patients with heart valve defects.

Chemoprophylaxis is reasonable when these patients undergo dental procedures if there is manipulation of gingival tissue or the periapical region of teeth or perforation of oral mucosa, but not for other dental procedures. Recommended therapy is a single dose of oral amoxicillin 30 min to 1 h before the procedure; intravenous ampicillin or ceftriaxone in those unable to take oral medication; or macrolide or clindamycin for patients allergic to β-lactam agents. Therapy may be administered no more than 2 h after the procedure for patients who failed to receive the prophylaxis prior to the procedure (Wilson et al., 2007).

Prophylaxis for Procedures on Infected Tissues

Prophylaxis is also reasonable for procedures that will involve infected skin and soft tissues as well as infected respiratory tract, but not in routine genitourinary and GI tract procedures. If the organism causing the infection is known, then the prophylactic antibiotic for patients undergoing these procedures should be tailored toward that organism.

Postexposure Prophylaxis

Postexposure prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorganisms to which they are exposed. Successful examples of this practice include rifampin administration to prevent meningococcal meningitis in people who are in close contact with a case, prevention of gonorrhea or syphilis after contact with an infected person, and macrolides after contact with confirmed cases of pertussis.

For HIV, there is now clear evidence to use antiretroviral therapy as part of prophylaxis in four situations: (1) immediate antiretroviral therapy for the partner in a serodiscordant couple; (2) preexposure prophylaxis for all population groups at substantial risk of HIV infection; (3) prevention of mother-to-child transmission; and (4) postexposure prophylaxis, which is after accidental exposure to HIV in body fluids. It is recommended that at least three drugs be administered for at least 28 days.

For influenza, the neuraminidase inhibitor oseltamivir is recommended for prevention of influenza A and B in healthy adults and children with close contact of laboratory-confirmed cases (Hayden and Pavia, 2006). Finally, mother-to-child transmission of syphilis is also an important public health problem for which specific chemotherapeutic regimens have been devised, based on locality. Prophylactic therapy for syphilis during pregnancy is effective in reducing neonatal death and infant neurological, auditory, and bone malformations.

Preemptive Therapy

Preemptive therapy is used as a substitute for universal prophylaxis and as early targeted therapy in high-risk patients who already have a laboratory or other test indicating that an asymptomatic patient is infected. The principle is that delivery of therapy prior to development of symptoms aborts impending disease, and the therapy is for a short and defined duration. This has been applied in the clinic to therapy for CMV after both hematopoietic stem cell transplants and after solid-organ transplantation (Gerna et al., 2008). When rapid turnaround tests (e.g., PCR based) are available, the preemptive strategy is now more preferable than universal prophylaxis for CMV.

Empirical Therapy in the Symptomatic Patient

Should a symptomatic patient be treated immediately? The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.

</table>

The first consideration in selecting an antimicrobial is to determine if the drug is indicated. The diagnosis may be masked if therapy is started and appropriate cultures are not obtained. Antimicrobial agents are potentially toxic and may promote selection of resistant microorganisms. For some diseases, the risk in waiting a few days is low, and these patients can wait for microbiological evidence of infection without empirical treatment. If the risks of waiting are high, based either on the patient’s immune status or other known risk factors, then initiation of optimal empirical antimicrobial therapy should rely on the clinical presentation and clinical experience. In addition, simple and rapid laboratory techniques are available for the examination of infected tissues.

The most valuable and time-tested method for immediate identification of bacteria is examination of the infected secretion or body fluid with Gram stain. In malaria-endemic areas, or in travelers returning from such an area, a simple thick-and-thin blood smear may mean the difference between a patient’s survival on appropriate therapy or death while on the wrong therapy for a presumed bacterial infection. On the other hand, neutropenic patients with fever have high risks of mortality, and when febrile, they are presumed to have either a bacterial or a fungal infection. Thus, a broad-spectrum combination of antibacterial and antifungal agents that cover common infections encountered in granulocytopenic patients is given. Performance of cultures is still mandatory with a view to modify antimicrobial therapy with culture results.

**Definitive Therapy With Known Pathogen**

Once a pathogen has been identified and susceptibility results are available, therapy should be streamlined to a narrow targeted antibiotic. Monotherapy is preferred to decrease the risk of antimicrobial toxicity and selection of antimicrobial-resistant pathogens. Proper antimicrobial doses and dose schedules are crucial to maximizing efficacy and minimizing toxicity. In addition, the duration of therapy should be as short as is necessary. Unecessarily prolonged therapies lead to the emergence of resistance.

Combination therapy is an exception, rather than a rule. Once a pathogen has been isolated, there should be no reason to use multiple antimicrobics, except when evidence overwhelmingly suggests otherwise. Using two antimicrobial agents where one suffices leads to increased toxicity and unnecessary damage to the patient’s protective fungal and bacterial flora. There are special circumstances where evidence favors combination therapy:

- preventing resistance to monotherapy;
- accelerating the rapidity of microbial kill;
CHEMOTHERAPY OF INFECTIOUS DISEASES

- enhancing therapeutic efficacy by use of synergistic interactions or enhancing kill by a drug based on a mutation generated by resistance to another drug;
- reducing toxicity (i.e., when sufficient efficacy of a single antibacterial agent can be achieved only at doses that are toxic to the patient and a second drug is coadministered to permit lowering the dose of the first drug)

Clinical situations for which combination therapy is advised include antiretroviral therapy for AIDS; antiviral therapy for hepatitis B and C; the treatment of tuberculosis, *M. avium-intracellulare*, and leprosy; fixed-dose combinations of antimarial drugs; the treatment of *Cryptococcus neoformans* with fluconazole and amphotericin B; during empirical therapy for patients with febrile neutropenia; and for advanced AIDS with fever.
The combination of a sulfonamide and an inhibitor of DHFR, such as trimethoprim, is synergistic owing to the inhibition of sequential steps in microbial folate synthesis; a fixed combination of sulfamethoxazole and trimethoprim is active against organisms that may be resistant to sulfonamides alone.

Posttreatment Suppressive Therapy

In some patients, the infection is controlled but not completely eradicated by the initial round of antimicrobial treatment, and the immunological or anatomical defect that led to the original infection is still present. In such patients, therapy is continued at a lower dose. This is common in patients with AIDS and patients posttransplant. The goal is more as secondary prophylaxis. Nevertheless, risks of toxicity from the long durations of therapy are still real. In this group of patients, the suppressive therapy is eventually discontinued if the patient's immune system improves.

Mechanisms of Resistance to Antimicrobial Agents

Antimicrobial agents were viewed as miracle cures when first introduced into clinical practice. However, as became evident soon after the discovery of penicillin, resistance develops and dims the luster of the miracle. This serious development is ever present with each new antimicrobial agent and threatens the end of the antimicrobial era. Today, every major class of antibiotic is associated with the emergence of significant resistance. Two major factors are associated with emergence of antibiotic resistance: evolution and clinical/environmental practices. When a microbial species is subjected to an existential threat, chemical or otherwise, that pressure will select for random mutations in the species' genome that permit survival. Pathogens will evolve to develop resistance to the chemical warfare to which we subject them. This evolution is greatly assisted by poor therapeutic practices by healthcare workers and the indiscriminate use of antibiotics in agriculture and animal husbandry.

Antimicrobial resistance can develop at any one or more of steps in the processes by which a drug reaches and combines with its target. Thus, resistance development may develop due to
- reduced entry of antibiotic into pathogen
- enhanced export of antibiotic by efflux pumps
- release of microbial enzymes that alter or destroy the antibiotic
- alteration of target proteins
- development of alternative pathways to those inhibited by the antibiotic

Mechanisms by which such resistance develops can include acquisition of genetic elements that code for the resistant mechanism, mutations that develop under antibiotic pressure, or constitutive induction.

Resistance Due to Reduced Entry of Drug Into Pathogen

The outer membrane of gram-negative bacteria is a semipermeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called *porins*. Absence of, mutation in, or loss of a favored porin channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that slows or abolishes this transport mechanism can confer resistance. For example, *Trypanosoma brucei* is treated with suramin and pentamidine during early stages, but with melarsoprol and eflornithine when CNS disease (sleeping sickness) is present. Melarsoprol is actively taken up by the *trypanosome F2* transporter. When the parasite lacks the F2 transporter or has a mutant form, resistance to melarsoprol and cross resistance to pentamidine occur due to reduced drug uptake (Ouellette, 2001).

Resistance Due to Drug Efflux

Microorganisms can overexpress efflux pumps and then expel antibiotics to which the microbes would otherwise be susceptible. There are five major systems of efflux pumps that are relevant to antimicrobial agents:
- The multidrug and toxin extruder
- The small multidrug resistance system
- The ABC transporters

Efflux pumps are a prominent mechanism of resistance for parasites, bacteria, and fungi. One of the tragic consequences of resistance emergence has been the development of drug resistance by *Plasmodium falciparum*. Drug resistance to most antimarial drugs, specifically chloroquine, quinine, mefloquine, halofantrine, lumefantrine, and the artemether-lumefantrine combination is mediated by an ABC transporter encoded by *P. falciparum* multidrug resistance gene 1 (*Pdr1*) (Happi et al., 2009). Point mutations in the *Pdr1* gene lead to drug resistance and failure of chemotherapy.

Drug efflux sometimes works in tandem with chromosomal resistance, as is seen in *Streptococcus pneumoniae* and *M. tuberculosis*. In these situations, induction of efflux pumps occurs early, which increases the MIC only modestly. However, this MIC increase may suffice to allow further microbial replication, a continuation of mutation, and the development of resistance via more robust chromosomal mutations (Gumbo et al., 2007b; Jumbe et al., 2006; Schmalslegl et al., 2012).

Resistance Due to Destruction of Antibiotic

Drug inactivation is a common mechanism of drug resistance. Bacterial resistance to aminoglycosides and to β-lactam antibiotics usually is due to production of an aminoglycoside-modifying enzyme or β-lactamase.

Resistance Due to Altered Target Structure

A common consequence of either single- or multiple-point mutations is a change in amino acid composition and conformation of an antimicrobial's target protein. This change can lead to reduced affinity of drug for its target or of a prodrug for the enzyme that activates the prodrug. Such alterations may be due to mutation of the natural target (e.g., *fluoroquinolone resistance*, target modification (e.g., ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (e.g., *staphylococcal methicillin resistance caused by production of a low-affinity penicillin-binding protein*) (Hooper, 2002; Lim and Strynadka, 2002; Nakajima, 1999). In HIV resistance, mutations associated with reduced affinity are encountered for protease inhibitors, integrase inhibitors, fusion inhibitors, and nonnucleoside reverse transcriptase inhibitors (Nijhuis et al., 2009). Similarly, benzimidazoles are used against myriad worms and protozoa and work by binding to the parasite's tubulin; point mutations in the β-tubulin gene lead to modification of the tubulin and drug resistance (Ouellette, 2001).

Incorporation of Drug

An uncommon situation occurs when an organism not only becomes resistant to an antimicrobial agent but also subsequently starts requiring
it for growth. Enterococcus, which easily develops vancomycin resistance, can, after prolonged exposure to the antibiotic, develop vancomycin-requiring strains. In 1955, shortly after introduction of streptomycin for tuberculosis, Hashimoto isolated a streptomycin-dependent mutant of *M. tuberculosis*; it grows in the presence of the antibiotic but goes into dormancy in the absence of the streptomycin.

### Resistance Due to Enhanced Excision of Incorporated Drug

Nucleoside reverse transcriptase inhibitors such as zidovudine are 2′-deoxyribonucleoside analogues that are converted to their 5′-triphosphate form and compete with natural nucleotides. These drugs are incorporated into the viral DNA chain and cause chain termination. When resistance emerges via mutations in the reverse transcriptase gene, phosphorolysis excision of the incorporated chain-terminating nucleoside analogue is enhanced (Arion et al., 1998).

### Heteroresistance and Viral Quasi-Species

Heteroresistance occurs when a subset of the total microbial population is resistant, despite the total population being considered susceptible on testing (Falagas et al., 2008; Rinder, 2001). A subclone that has alterations in genes associated with drug resistance is expected to reflect the normal mutation rates (occurrence in 1 in 10<sup>4</sup> to 10<sup>10</sup> colonies). In bacteria, heteroresistance has been described especially for vancomycin in *S. aureus* and *Enterococcus faecium*; colistin in *Acinetobacter baumannii-calcoaceti*; rifampin, isoniazid, and streptomycin in *M. tuberculosis*; and penicillin in *S. pneumoniae* (Falagas et al., 2008; Rinder, 2001). Increased therapeutic failures and mortality have been reported in patients with heteroresistant staphylococci and *M. tuberculosis* (Falagas et al., 2008; Hofmann-Thiel et al., 2009). For fungi, heteroresistance leading to clinical failure has been described for fluconazole in *C. neoformans* and *Candida albicans* (Marr et al., 2001; Mondon et al., 1999).

Viral replication is more error prone than replication in bacteria and fungi. Viral evolution under drug and immune pressure occurs relatively easily, commonly resulting in variants or quasi-species that may contain drug-resistant subpopulations. This is not often termed heteroresistance, but the principle is the same: A virus may be considered susceptible to a drug because either phenotypic or genotypic tests reveal “lack” of resistance, even though there is a resistant subpopulation just below the limit of assay detection. These minority quasi-species that are resistant to antiretroviral agents have been associated with failure of antiretroviral therapy (Metzner et al., 2009).

### Evolutionary Basis of Resistance Emergence

#### Development of Resistance via Mutation Selection

Mutations are random events that confer a survival advantage when drug is present. Mutation and antibiotic selection of resistant mutants are the molecular basis for resistance for many bacteria, viruses, and fungi. Mutations may occur in the gene encoding the following:

- the target protein, altering its structure so that it no longer binds the drug
- a protein involved in drug transport
- a protein important for drug activation or inactivation
- in a regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme

In some instances, a single-step mutation results in a high degree of resistance. In *M. tuberculosis katG*, Ser315 mutations cause resistance to isoniazid; the M814V mutation in the reverse transcriptase gene of HIV-1 causes resistance to lamivudine; and *C. albicans fks1* Ser645 mutations cause resistance to echinocandins.

In other circumstances, however, it is the sequential acquisition of multiple mutations that leads to clinically significant resistance. For example, the combination of pyrimethamine (an inhibitor of DHFR) and sulfadoxine (an inhibitor of DHPS) blocks the folate biosynthetic pathway in *P. falciparum*. Clinically meaningful resistance occurs only when there is a single-point mutation in the DHPS gene accompanied by at least a double mutation in the DHFR gene.

#### Hypermutable Phenotypes

Genetic continuity is accomplished principally by the replicative and repair activities of DNA polymerases and postreplicative repair systems. The development of a defect in one of these repair mechanisms leads to a high degree of mutations in many genes; such isolates are termed *mutator* (*Mut*) *phenotypes* and may include mutations in genes causing antibiotic resistance (Giraud et al., 2002). This second-order selection of hypermutable (mutator) alleles based on alterations in DNA repair genes has been implicated in the emergence of multidrug-resistant strains of *M. tuberculosis* Beijing genotype (Rad et al., 2003).

### Resistance by External Acquisition of Genetic Elements

As described, drug resistance may be acquired by mutation and selection, with passage of the trait vertically to daughter cells, provided the mutation is not lethal, does not appreciably alter virulence, and does not affect replication by the progeny. Drug resistance more commonly is acquired by horizontal transfer of resistance determinants from a donor cell, often of another bacterial species, by transduction, transformation, or conjugation. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain or by subsequent transfers to other susceptible recipient strains. Horizontal transfer of resistance offers several advantages over mutation selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes. The gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells, and the resistance gene can be eliminated when it no longer offers a selective advantage.

#### Horizontal Gene Transfer

Horizontal transfer of resistance genes is greatly facilitated by mobile genetic elements. Mobile genetic elements include plasmids and transducing phages. Other mobile elements—transposable elements, integrons, and gene cassettes—also participate. Transposable elements are of three general types: insertion sequences, transposons, and transposable phages.

Only insertion sequences and transposons are important for resistance. There are numerous modes of horizontal resistance transfer:

- **Insertion sequences** are short segments of DNA encoding enzymatic functions (e.g., transposase and resolvase) for site-specific recombination with inverted repeat sequences at either end. They can copy themselves and insert themselves into a chromosome or a plasmid. Insertion sequences do not encode resistance, but they function as sites for integration of other resistance-encoding elements (e.g., plasmids or transposons).
- **Transposons** are insertion sequences, mobile elements that excise and integrate in the bacterial genomic or plasmid DNA (i.e., from plasmid to plasmid, from plasmid to chromosome, or from chromosome to plasmid). Basically, a resistance gene can “hitchhike” with a transferable element out of the host and into a recipient.
- **Integrons** are not formally mobile and do not copy themselves, but they encode an integrase and provide a specific site into which mobile gene cassettes integrate.
- **Gene cassettes** encode resistance determinants, usually lacking a promoter, with a downstream repeat sequence. The integrase recognizes this repeat sequence and directs insertion of the cassette into position behind a strong promoter that is present on the integron. Integrons may be located within transposons or in plasmids and therefore may be mobilizable or located on the chromosome.
- **Transduction** is the acquisition of bacterial DNA from a phage (a virus that propagates in bacteria) that has incorporated DNA from a previous host bacterium within its outer protein coat. If the DNA includes a...
gene for drug resistance, the newly infected bacterial cell may acquire resistance. Transduction is particularly important in the transfer of antibiotic resistance among strains of **S. aureus**.

- **Transformation** is the uptake and incorporation into the host genome by homologous recombination of free DNA released into the environment by other bacterial cells. Transformation is the molecular basis of penicillin resistance in pneumococci and **Neisseria**.

**Conjugation** is gene transfer by direct cell-to-cell contact through a sex pilus or bridge, allowing the transfer of multiple resistance genes in a single event. The transferable genetic material consists of two different sets of plasmid-encoded genes on the same or different plasmids: one encoding the actual resistance, and another encoding genes necessary for bacterial conjugation. Conjugation with genetic exchange between nonpathogenic and pathogenic microorganisms probably occurs in the GI tract. The efficiency of transfer is low; however, antibiotics can exert a powerful selective pressure to allow emergence of the resistant strain. Genetic transfer by conjugation is common among gram-negative bacilli, and resistance is conferred on a susceptible cell as a single event. Enterococci also contain a broad range of host-range conjugative plasmids that are involved in the transfer and spread of resistance genes among gram-positive organisms.

Global Impact of Malaria

Malaria remains among the top five causes of death among children younger than 5 years, affects about a quarter of a billion people, and causes almost 900,000 deaths annually (GBD_2013_Collaborators, 2015). Malarial transmission occurs in regions of Africa, Latin and South America, Asia, the Middle East, the South Pacific, and the Caribbean (Figure 53–1). This disease is caused by infection with protozoan parasites of the genus Plasmodium. Five Plasmodium spp. are known to infect humans: P. falciparum, P. vivax, P. ovale, P. malariae, and P. knowlesi. Plasmodium falciparum and P. vivax cause most malarial infections worldwide. Plasmodium falciparum accounts for the majority of the burden of malaria in sub-Saharan Africa and is associated with the most severe disease. Plasmodium vivax accounts for half of the malaria burden in South and East Asia and more than 80% of the malarial infections in the Americas and has been underappreciated as a cause of severe malaria (Baird, 2013).

Over the past half-century, malaria parasites worldwide—primarily P. falciparum and P. vivax—have become increasingly resistant to anti-malarial drugs, including chloroquine (Djinde et al., 2001; Warhurst, 2001); mefloquine (White et al., 2014); quinine (White et al., 2014); sulfadoxine/pyrimethamine (Artimovich et al., 2015; Plowe et al., 1995, Sibley et al., 2001); and atovaquone (Garcia-Bustos et al., 2013; Kessel et al., 2007). In response, new, multipartner international public–private partnerships as well as other funding agencies and sources have emerged to create new pipelines that advance drug candidates from discovery to clinical development (Hemingway et al., 2016; Wells et al., 2010, 2015).

Biology of Malarial Infection

Malarial infection is initiated when a female anopheline mosquito injects Plasmodium sporozoites during a blood meal (Miller et al., 1998). After entering the dermis, sporozoites enter the bloodstream and, within minutes, arrive at the liver, where they infect individual hepatocytes via cell surface receptor-mediated events (Sinnis et al., 2013). This process initiates the asymptomatic prepatent period, or exoerythrocytic stage of infection, which typically lasts about 1 week.

During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver-stage schizonts. When an infected hepatocyte ruptures, tens of thousands of merozoites are released into the bloodstream and infect red blood cells. After the initial exoerythrocytic stage, P. falciparum and P. malariae are no longer found in the liver. Plasmodium vivax and P. ovale, however, can maintain a quiescent hepatocyte infection as a dormant form of the parasite known as the hypnozoite and can reinitiate symptomatic disease long after the initial symptoms of malaria are recognized and treated. Exoerythrocytic forms cannot reestablish infection of hepatocytes. Transmission of human-infecting malarial parasites is maintained in human populations by the persistence of hypnozoites (several months to a few years for P. vivax and P. ovale), by antigenic variation in P. falciparum (probably months), and by the putative antigen variation in P. malariae (for as long as several decades).

The asexual erythrocytic stages of malarial parasites are responsible for the clinical manifestations of malaria. This part of the Plasmodium life cycle is initiated by merozoite recognition of red blood cells and mediated by cell surface receptors that facilitate invasion of red blood cells.

Once inside a red blood cell, the merozoite develops into a ring form, which becomes increasingly resistant to anti-malarial drugs, including chloroquine (Djinde et al., 2001; Warhurst, 2001); mefloquine (White et al., 2014); quinine (White et al., 2014); sulfadoxine/pyrimethamine (Artimovich et al., 2015; Plowe et al., 1995, Sibley et al., 2001); and atovaquone (Garcia-Bustos et al., 2013; Kessel et al., 2007). In response, new, multipartner international public–private partnerships as well as other funding agencies and sources have emerged to create new pipelines that advance drug candidates from discovery to clinical development (Hemingway et al., 2016; Wells et al., 2010, 2015).

Global Impact of Malaria

In response, new, multipartner international public–private partnerships as well as other funding agencies and sources have emerged to create new pipelines that advance drug candidates from discovery to clinical development (Hemingway et al., 2016; Wells et al., 2010, 2015).

Biology of Malarial Infection

Malarial infection is initiated when a female anopheline mosquito injects Plasmodium sporozoites during a blood meal (Miller et al., 1998). After entering the dermis, sporozoites enter the bloodstream and, within minutes, arrive at the liver, where they infect individual hepatocytes via cell surface receptor-mediated events (Sinnis et al., 2013). This process initiates the asymptomatic prepatent period, or exoerythrocytic stage of infection, which typically lasts about 1 week.

During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver-stage schizonts. When an infected hepatocyte ruptures, tens of thousands of merozoites are released into the bloodstream and infect red blood cells. After the initial exoerythrocytic stage, P. falciparum and P. malariae are no longer found in the liver. Plasmodium vivax and P. ovale, however, can maintain a quiescent hepatocyte infection as a dormant form of the parasite known as the hypnozoite and can reinitiate symptomatic disease long after the initial symptoms of malaria are recognized and treated. Exoerythrocytic forms cannot reestablish infection of hepatocytes. Transmission of human-infecting malarial parasites is maintained in human populations by the persistence of hypnozoites (several months to a few years for P. vivax and P. ovale), by antigenic variation in P. falciparum (probably months), and by the putative antigen variation in P. malariae (for as long as several decades).

The asexual erythrocytic stages of malarial parasites are responsible for the clinical manifestations of malaria. This part of the Plasmodium life cycle is initiated by merozoite recognition of red blood cells and mediated by cell surface receptors that facilitate invasion of red blood cells.

Once inside a red blood cell, the merozoite develops into a ring form, which becomes increasingly resistant to anti-malarial drugs, including chloroquine (Djinde et al., 2001; Warhurst, 2001); mefloquine (White et al., 2014); quinine (White et al., 2014); sulfadoxine/pyrimethamine (Artimovich et al., 2015; Plowe et al., 1995, Sibley et al., 2001); and atovaquone (Garcia-Bustos et al., 2013; Kessel et al., 2007). In response, new, multipartner international public–private partnerships as well as other funding agencies and sources have emerged to create new pipelines that advance drug candidates from discovery to clinical development (Hemingway et al., 2016; Wells et al., 2010, 2015).
knobs that are presented on the erythrocyte surface (Hviid et al., 2015; Ukaegbu et al., 2015). Knobs allow the P. falciparum-parasitized erythrocyte to bind to postcapillary vascular endothelium to avoid spleen-mediated clearance and allow the parasite to grow in a low-O₂, high-CO₂ microenvironment.

## Clinical Manifestations of Malaria

The cardinal signs and symptoms of malaria are high, spiking fevers (with or without periodicity), chills, headaches, myalgias, malaise, and GI symptoms (White et al., 2014). Severe headache, a characteristic early symptom in malaria caused by all Plasmodium spp., often heralds the onset of disease, even before fever and chills. Plasmodium falciparum causes the most severe disease and may lead to organ failure and death. Plasmodial malaria, of particular danger for primigravidae, is due to P. falciparum adherence to CSA in the placenta. This often leads to severe complications, including miscarriage. When treated early, symptoms of malarial infection usually improve within 24–48 h. New insights into malaria clinical presentations indicate that—in the endemic setting where nonsterilizing clinical immunity is the rule, not the exception—the cardinal symptoms of malaria may be atypical or absent (Chen et al., 2016).

Acute illness due to P. vivax infection may appear severe due to high fever and prostration. Indeed, the pyrogenic threshold of this parasite (i.e., “blood stage” parasite burden associated with fever) is lower than that of P. falciparum. Nonetheless, P. vivax malaria generally has a low mortality rate. Plasmodium vivax malaria is characterized by relapses caused by the reactivation of latent tissue forms. Clinical manifestations of relapse are the same as those of primary infection. In recent years, severe P. vivax malaria from Oceania (Papua New Guinea, Indonesia) and India possess important similarities to severe malaria caused by P. falciparum. These include neurological symptoms (diminished consciousness, seizure) and pulmonary edema. Rare but life-threatening complications can occur, including splenic rupture, acute lung injury, and profound anemia.

Plasmodium ovale causes a clinical syndrome similar to that of P. vivax but may be milder with lower levels of parasitemia. It shares with P. vivax the ability to form the hypnozoite (dormant liver stage) that may relapse after months to 2 years later. Plasmodium ovale is more common in sub-Saharan Africa and some islands in Oceania.

Plasmodium malariae generally causes an indolent infection with very low levels of parasitemia and often does not produce clinical symptoms. This parasite can be found in all malaria-endemic areas but is most common in sub-Saharan Africa and the southwest Pacific. Interestingly, P. malariae prevalence increases during the dry season and can be found as a coinfection with P. falciparum. An uncommon but potentially fatal complication of P. malariae is a glomerulonephritis syndrome that does not respond to antimalarial treatment.

Plasmodium knowlesi infection is often misdiagnosed as P. malariae by light microscopy. This infection is distinguished by a shorter erythrocytic cycle (24 h compared with 72 h for P. malariae) and higher levels of parasitemia. Like P. malariae, P. knowlesi is generally sensitive to chloroquine, but patients presenting with advanced disease nonetheless may progress to death despite adequate drug dosing.

Asymptomatic P. falciparum and P. vivax infections are common in endemic regions and represent important potential reservoirs for malaria transmission. Although different studies are not entirely consistent in the definition of asymptomatic, generally this state implies a lack of fever, headache, and other systemic complaints, within a defined time period prior to a positive test for malaria parasitemia. Migration of asymptomatic individuals to areas where malaria is not present but vector mosquitoes are (i.e., anophelism without malaria) is an important mechanism for the introduction or reintroduction of malaria, in addition to facilitating the spread of drug-resistant isolates. Novel approaches to preventing transmission from asymptomatic reservoirs—whether through new drugs or vaccines—will be essential for future malaria control, elimination, and eradication strategies.

## Classification of Antimalarial Agents

The various stages of the malarial parasite life cycle in humans differ in their drug sensitivity. Thus, antimalarial drugs can be classified based on their activities during this life cycle as well as by their intended use for either chemoprophylaxis or treatment. The spectrum of antimalarial drug activity leads to several generalizations.

The first relates to chemoprophylaxis: Because no antimalarial drug kills sporozoites, it is not truly possible to prevent infection; drugs can only prevent the development of symptomatic malaria caused by the asexual erythrocytic forms, either in the bloodstream or as produced within and released by hepatocytes prior to erythrocyte invasion.

The second relates to the treatment of an established infection: No single antimalarial is effective against all hepatic and intraerythrocytic stages of the life cycle that may coexist in the same patient. Complete elimination of the parasite infection, therefore, may require more than one drug.

The patterns of clinically useful antimalarial agents fall into three general categories (Table 53–1):

1. **Agents (artemisinins, chloroquine, mefloquine, quinine and quinidine, pyrimethamine, sulfadoxine, and tetracycline)** that are not reliably effective against primary or latent liver stages. Instead, their action is directed against the asexual blood stages responsible for disease. These drugs will treat, or prevent, clinically symptomatic malaria.

2. **Drugs (typified by atovaquone and proguanil)** that target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure chemoprophylaxis.

3. **Primaquine**, an eight-amino quinolone that is effective against primary and latent liver stages as well as gametocytes. Primaquine is used most commonly to eradicate the intrahepatic hypnozoites of *P. vivax* and *P. ovale* that are responsible for relapsing infections. Tafenoquine, an eight-amino quinolone, is a long half-life analogue of primaquine, has a similar spectrum of action as primaquine, and is in advanced clinical trials (Llanos-Cuentas et al., 2014).

Aside from their antiparasitic activity, the utility of antimalarials for chemoprophylaxis or therapy depends on their pharmacokinetics and
CHEMOTHERAPY OF INFECTIOUS DISEASES
SECTION VII
CHEMOTHERAPY OF INFECTIOUS DISEASES

Figure 53–1  Malaria-endemic countries.  A. Eastern Hemisphere; B. Western Hemisphere. A country is shaded orange even if malaria is endemic in just a portion of that country. Large regions not shown on the maps (e.g., Scandinavia, Russia, Canada, U.S.A., Tasmania, New Zealand) are non-endemic for malaria. (Reproduced from Centers for Disease Control and Prevention. https://wwwnc.cdc.gov/travel/yellowbook/2018/infectious-diseases-related-to-travel/malaria; accessed July 29, 2017). In areas of endemic malaria, the disease is largely chloroquine-resistant. For up-to-date information, consult the online CDC Malaria Map (https://www.cdc.gov/malaria/travelers/about_maps.html) and the CDC's Malaria Information and Prophylaxis, by Country (http://www.cdc.gov/malaria/travelers/country_table/a.html).
safety. Quinine and primaquine, which have significant toxicity and relatively short half-lives, generally are reserved for the treatment of established infection and are not used for chemoprophylaxis in a healthy traveler. By contrast, chloroquine, which is relatively free from toxicity and has a long \( t_{1/2} \), is convenient for chemoprophylactic dosing (in those few areas still reporting chloroquine-sensitive malaria).

Specific Antimalarial Agents

For ease of reference, detailed information on the antimalarial drugs appears next in alphabetical order by drug name.

Artemisinin and Its Derivatives

Artemisinin and its three major semisynthetic derivatives in clinical use, dihydroartemisinin, artemether, and artesunate, are potent and fast-acting antimalarials. They are optimized for the treatment of severe \( P. falciparum \) malaria and are also effective against the asexual erythrocytic stages of \( P. vivax \). Increasingly, the standard treatment of malaria employs artemisinin-based combination therapies (ACTs) to increase treatment efficacy and reduce selection pressure for the emergence of drug resistance. Recent reports of \( P. falciparum \) artemisinin “resistance” do not indicate true resistance but reflect delayed parasite clearance time on the order of hours (Ashley et al., 2014; Huang et al., 2015); mutations in the \( P. falciparum \) gene \( PfK13 \) encoding the kelch13 propeller protein have been associated with these delayed parasite clearance times, although the mechanism by which the kelch13 propeller protein mediates delayed parasite clearance remains unknown. True resistance to artemisinin has not been reported, and no infection from this parasite has been reported to survive ACT due to delayed clearance times (van Schalkwyk et al., 2015). The clinical significance of \( P. falciparum \) artemisinin “resistance/delayed clearance” remains unclear (Fairhurst, 2015), but this mutation potential could threaten the future utility of this drug class. Moreover, in the presence of mutations that confer resistance to partner drugs (e.g., the ACT partner
drug piperaquine), clinically significant ACT failure is substantial, with recrudescence rates reported to exceed 50% (Amaratunga et al., 2016; Spring et al., 2015). Resistance of non-\textit{P. falciparum} malaria parasites to artemisinin class drugs has not been reported.

Artemisinins cause a significant reduction of the parasite burden, with a 4-log \textsubscript{10} reduction in the parasite population for each 48-h cycle of intraerythrocytic invasion, replication, and egress. Only three to four cycles (6–8 days) of treatment are required to remove all the parasites from the blood. In addition, artemisinins possess some gametocytocidal activity, leading to a decrease in malarial parasite transmission.

**Mechanism of Action**

The activity of artemisinin and derivatives seems to result from cleavage of the drug’s peroxide bridge by reduced heme-iron, produced inside the highly acidic digestive vacuole of the parasite as it digests hemoglobin. The site of action of the putatively toxic heme-adducts is unclear. In addition, activated artemisinin might in turn generate free radicals that alkylate and oxidize macromolecules in the parasite.

**ADME**

The semisynthetic artemisinins have been formulated for oral (dihydroartemisinin, artesunate, and artemether); intramuscular (artesunate and artemether); intravenous (artesunate); and rectal (artesunate) routes. Bioavailability after oral dosing typically is 30% or less. Peak serum levels occur rapidly with artemisinins and in 2–6 h with intramuscular artemether. Both artesunate and artemether have modest levels of plasma protein binding, ranging from 43% to 82%. These derivatives are extensively metabolized and converted to dihydroartemisinin, which has a plasma \textit{t}\textsubscript{1/2} of 1–2 h. Drug bioavailability via rectal administration is highly variable among individual patients. With repeated dosing, artemisinin and artesunate induce their own CYP-mediated metabolism, primarily via CYPs 2B6 and 3A4, which may enhance clearance by as much as 5-fold.

**Therapeutic Uses**

Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the treatment of severe \textit{P. falciparum} malaria. The artemisinins generally are not used alone because of their limited ability to eradicate infection completely. Artemisinins are highly effective for the first-line treatment of malaria when combined with other antimalarials. Artemisinins should not be used for chemoprophylaxis because of their short \textit{t}\textsubscript{1/2} values.

**Toxicity and Contraindications**

In pregnant rats and rabbits, artemisinins can cause increased embryo lethality or malformations early postconception. Preclinical toxicity studies have identified the brain (and brainstem), liver, and bone marrow as the principal target organs. However, no systematic neurological changes have been attributed to treatment in patients 5 years of age or older. Patients may develop dose-related and reversible decreases in reticuloocyte and neutrophil counts and increases in transaminase levels. About 1 in 3000 patients develops an allergic reaction. Although studies of artemisinin treatment during the first trimester of pregnancy have found no evidence of adverse effects on fetal development, it is recommended that ACTs not be used during the first trimester of pregnancy or for the treatment of children 5 kg or less.

**ACT Partner Drugs**

Partner drugs for ACT are chosen for potency and \textit{t}\textsubscript{1/2}, that substantially exceeds that of the artemisinin partner. The primary ACT regimens that are well tolerated in adults and children 5 kg or more are artemether-lumefantrine, artesunate-amodiaquine, and dihydroartemisinin-piperaquine. In the U.S., artemether-lumefantrine is probably the drug of choice for all malaria cases if oral drug treatment is appropriate. Pyronaridine remains in clinical trials and is not licensed.

- **Lumefantrine** shares structural similarities with the arylamino alcohol drugs mefloquine and halofantrine and is formulated with artemether. This combination is highly effective for the treatment of uncomplicated malaria and is the most widely used first-line antimalarial across Africa. The pharmacokinetic properties of lumefantrine include a large apparent volume of distribution and a terminal elimination \textit{t}\textsubscript{1/2} of 4–5 days. Administration with a high-fat meal is recommended because it significantly increases absorption. A sweetened dispersible formulation of artemether-lumefantrine has been approved for treatment of children.

- **Amodiaquine** is a congener of chloroquine that is no longer recommended in the U.S. for chemoprophylaxis of \textit{P. falciparum} malaria because of toxicities (hepatic and agranulocytosis) generally associated with its prophylactic use. Amodiaquine is rapidly converted by hepatic CYPs into monodesethyl-amodiaquine. This metabolite, which retains substantial antimalarial activity, has a plasma \textit{t}\textsubscript{1/2} of 9–18 days and reaches a peak concentration of about 500 nM 2 h after oral administration of the recommended dose. By contrast, amodiaquine has a \textit{t}\textsubscript{1/2} of about 3 h, attaining a peak concentration of about 25 nM within 30 min of oral administration. Clearance rates of amodiaquine vary widely among individuals (78–943 mL/min/kg).

- **Piperazine** is a potent and well-tolerated bisquinoline compound structurally related to chloroquine. Piperaquine has a large volume of

Atovaquone

A fixed combination of atovaquone with proguanil hydrochloride is available in the U.S. for malaria chemoprophylaxis and for the treatment of uncomplicated *P. falciparum* malaria in adults and children.

**Mechanism of Action, Selective Toxicity, Antimalarial Action, and Resistance**

Atovaquone is a lipophilic analogue of ubiquinone (coenzyme Q), the electron acceptor for the parasite's cytochrome bc1 complex. Cytochrome bc1, situated on the inner mitochondrial membrane, supplies oxidized ubiquinone for dihydroorotate dehydrogenase, an essential enzyme in pyrimidine biosynthesis in the parasite. In addition, cytochrome bc1 is part of the respiratory chain and transports $H^+$ into the intramembranous space of mitochondria. By binding at the Q$_0$ site of cytochrome bc1, atovaquone inhibits electron transport, collapses the mitochondrial membrane potential, and inhibits regeneration of ubiquinone. The selective toxicity of atovaquone for the *Plasmodium* genus and not the human host may stem from structural differences in the amino terminal regions of plasmodial and human cytochrome b (Capper et al., 2015).

The drug is highly active against *P. falciparum* asexual blood-stage parasites and the liver stages of *P. falciparum*, but not against *P. vivax* liver-stage hypnozoites. Synergy between proguanil and atovaquone results from the ability of nonmetabolized proguanil to enhance the mitochondrial toxicity of atovaquone. Resistance to atovaquone alone in *P. falciparum* develops easily and is conferred by single, nonsynonymous nucleotide polymorphisms in the cytochrome b gene located in the mitochondrial genome. Addition of proguanil markedly reduces the frequency of appearance of atovaquone resistance. However, once atovaquone resistance is present, the synergy of the partner drug proguanil diminishes.

**ADME**

Atovaquone absorption is slow and variable after an oral dose; absorption improves when the drug is taken with a fatty meal. More than 99% of the drug is bound to plasma protein; CSF levels are less than 1% of those in plasma. Profiles of drug concentration versus time often show a double peak, the first at 1–8 h, the second 1–4 days after a single dose; this pattern suggests enterohepatic circulation. Humans do not metabolize atovaquone significantly. The drug is excreted in bile, and more than 94% of the drug is recovered unchanged in feces. Atovaquone has a reported elimination $t_{1/2}$ from plasma of 2–3 days in adults and 1–2 days in children.

**Therapeutic Uses**

A tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride, taken orally, is highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of chloroquine- or sulfadoxine-pyrimethamine-resistant *P. falciparum* malaria. The same regimen followed by a primaquine course is effective in treatment of *P. vivax* malaria. Atovaquone-proguanil is a standard agent for malaria chemoprophylaxis. Experience in prevention of non-*P. falciparum* malaria is limited. *Plasmodium vivax* infection may occur after drug discontinuation, indicating imperfect activity against exoerythrocytic stages of this parasite.

**Toxicity**

Atovaquone may cause side effects (abdominal pain, nausea, vomiting, diarrhea, headache, rash) that require cessation of therapy. Vomiting and diarrhea may decrease drug absorption, resulting in therapeutic failure. However, readministration of this drug within an hour of vomiting may still be effective in patients with *P. falciparum* malaria. Atovaquone occasionally causes transient elevations of serum transaminase or amylase.

**Precautions and Contraindications**

Although atovaquone is generally considered to be safe, it needs further evaluation in children weighing less than 11 kg, pregnant women, and lactating mothers. Atovaquone may compete with certain drugs for binding to plasma proteins. Therapy with rifampin reduces plasma levels of atovaquone substantially; the mechanism of this effect is not clear. Coadministration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

**Diaminopyrimidines**

Sulfadoxine-pyrimethamine was a primary treatment of uncomplicated *P. falciparum* malaria, especially against chloroquine-resistant strains. Due to widespread resistance, it is no longer recommended for the treatment of uncomplicated malaria.
Antimalarial Action and Resistance
Pyrimethamine is a slow-acting blood schizontocide with antimalarial effects in vivo resulting from inhibition of folate biosynthesis in Plasmodium, similar to proguanil. The efficacy of pyrimethamine against hepatic forms of P. falciparum is less than that of proguanil. At therapeutic doses, pyrimethamine fails to eradicate P. vivax hypnozoites or gametocytes of any Plasmodium species. The drug increases the number of circulating P. falciparum mature infecting gametocytes, likely leading to increased transmission to mosquitoes during the period of treatment.

Synergy of pyrimethamine and the sulfonamides or sulphones results from inhibition of two metabolic steps in folate biosynthesis in the parasite:

- the utilization of p-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides; and
- the reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by pyrimethamine (see Figure 56–2).

Dietary p-aminobenzoic acid or folate may affect the therapeutic response to antifolates. Resistance to pyrimethamine has developed in regions of prolonged or extensive drug use and can be attributed to mutations in dihydrofolate reductase that decrease the binding affinity of pyrimethamine.

ADME
Oral pyrimethamine is slowly but completely absorbed, reaching peak plasma levels in 2–6 h. The compound is significantly distributed in the tissues and is about 90% bound to plasma proteins. Pyrimethamine is slowly eliminated from plasma, with a half-life of about 85–100 h. Concentrations that are suppressive for sensitive Plasmodium strains remain in the blood for about 2 weeks. Pyrimethamine also enter the milk of nursing mothers.

Therapeutic Uses
Due to increasing drug resistance, pyrimethamine-sulfadoxine is no longer recommended for the treatment of uncomplicated malaria or for chemoprophylaxis. However, for those living in malaria-endemic areas, some still recommend it for the intermittent preventive treatment of malaria in pregnancy.

Toxicity, Precautions, and Contraindications
Antimalarial doses of pyrimethamine alone cause minimal toxicity except for occasional skin rashes and reduced hematopoiesis. Excessive doses can produce a megaloblastic anemia, resembling that of folate deficiency, which responds readily to drug withdrawal or treatment with folic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans the related combination, trimethoprim-sulfamethoxazole, may cause birth defects.

Sulfonamides or sulphones, rather than pyrimethamine, usually account for the toxicity associated with coadministration of these antifolate drugs. The combination of pyrimethamine and sulfadiazine causes severe and even fatal cutaneous reactions, such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. It has also been associated with serum sickness-type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine-sulfadoxine is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants less than 2 months of age. Administration of pyrimethamine with dapsone, a drug combination unavailable in the U.S., has occasionally been associated with agranulocytosis.

Proguanil
The antimalarial activity of proguanil (chloroguanide) is ascribed to cycloguanil, a cyclic triazine metabolite (structurally related to pyrimethamine) and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase-thymidylate synthetase that is crucial for parasite de novo purine and pyrimidine synthesis.

Antimalarial Action and Resistance
In drug-sensitive P. falciparum malaria, proguanil exerts activity against both the primary liver stages and the asexual red blood cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil is also active against acute P. vivax malaria, but because the latent tissue stages of P. vivax are unaffected, relapses may occur after the drug is withdrawn. Proguanil treatment does not destroy gametocytes, but oocysts in the gut of the mosquito can fail to develop normally.

Cycloguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors. A series of amino acid changes near the dihydrofolate reductase–binding site have been identified that cause resistance to cycloguanil, pyrimethamine, or both.

The presence of Plasmodium dihydrofolate reductase is not required for the intrinsic antimalarial activity of proguanil or chlorproguanil; however, the molecular basis for this alternative activity is unknown. Proguanil accentuates the mitochondrial membrane-potential–collapsing action of atovaquone against P. falciparum but displays no such activity by itself. In contrast to cycloguanil, resistance to the parent drug, proguanil, either alone or in combination with atovaquone, is not well documented.

ADME
Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak plasma concentrations are attained within 5 h. The mean plasma elimination half-life is about 180–200 h or longer. The drug's activation and metabolism involve the CYP2C subfamily; about 30% of whites are deficient in this oxidation phenotype, contrasted with about 20% of Asians and Kenyans. Proguanil is oxidized to two major metabolites, the active cycloguanil and an inactive 4-chlorophenyl biguanide. On a daily dosage regimen of 200 mg-daily, plasma levels of cycloguanil in extensive metabolizers exceed the therapeutic range, whereas cycloguanil levels in poor metabolizers do not. Proguanil itself does not accumulate appreciably in tissues during long-term administration, except in red blood cells, where its concentration is about three times that in plasma. In humans, 40%–60% of the absorbed proguanil is excreted in urine, either as the parent drug or as the active metabolite.

Therapeutic Uses
Proguanil as a single agent is not available in the U.S. but has been prescribed as chemoprophylaxis in England and Europe for individuals traveling to malarious areas in Africa. Strains of P. falciparum resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections may also result from deficient conversion of proguanil to its active antimalarial metabolite. Proguanil is effective and tolerated well in combination with atovaquone, once daily for 3 days, to treat drug-resistant strains of P. falciparum or P. vivax (see section on atovaquone). P. falciparum readily develops clinical resistance to monotherapy with either proguanil or atovaquone; however, resistance to the combination is uncommon unless the strain is initially resistant to atovaquone.

Toxicity and Side Effects
In chemoprophylactic doses of 200–300 mg daily, proguanil causes relatively few adverse effects, except occasional nausea and diarrhea. Large doses (≥1 g daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Doses as high as 700 mg twice daily have been taken for more than 2 weeks without serious toxicity. Proguanil is safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs.

Quinolines and Related Compounds
Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree. Quinine and its many derivatives have been the mainstay of malarial treatment for four centuries. Structure-
Chloroquine resistance results from mutations in the PfMRP gene that encodes a putative transporter that may play a modulatory role in chloroquine resistance. The P-glycoprotein transporter encoded by pfmdr1, and other transporters, including P. falciparum multidrug resistance-associated protein (PMPRP), may also result from overdose. Chloroquine doses of more than 5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs most commonly among dark-skinned persons. Prolonged treatment with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleeding of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes. This drug has also been reported to interfere with the immunogenicity of certain vaccines. Irreversible retinopathy and ototoxicity can result from high daily doses (>250 mg) of chloroquine or hydroxychloroquine leading to cumulative total doses of more than 1 g/kg. Retinopathy presumably is related to drug accumulation in melanin-containing tissues and can be avoided if the daily dose is 250 mg or less. Prolonged therapy with high doses of chloroquine or hydroxychloroquine also can cause toxic myopathy, cardiopathy, and peripheral neuropathy. These reactions improve if the drug is withdrawn promptly. Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

Precautions and Contraindications. Chloroquine is not recommended for treating individuals with epilepsy or myasthenia gravis and should be used cautiously, if at all, in the presence of advanced liver disease or severe GI, neurological, or blood disorders. The dose should be reduced in renal failure. In rare cases, chloroquine can cause hemolysis in patients with G6PD deficiency. Chloroquine should not be prescribed for patients with porphyria or other exfoliative skin conditions. It should not be used to treat malaria in patients with porphyria cutanea tarda; however, it can be used in lower doses for treatment of manifestations of this form of porphyria.

Chloroquine inhibits CYP2D6 and thus can interact with a variety of different drugs. It attenuates the efficacy of the yellow fever vaccine when administered at the same time. It should not be given with mefloquine because of increased risk of seizures. Chloroquine opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias when coadministered with amiodarone or halofantrine. By increasing plasma levels of digoxin and cyclosporine, chloroquine can increase the risk of toxicity from these agents. Patients receiving long-term, high-dose therapy instituted with quinine plus tetracycline or doxycycline or with atovaquone-proguanil, artemether-lumefantrine, or mefloquine if the others are not available. In comatose children, chloroquine is well absorbed and effective when given through a nasogastric tube. Tables 53–2 and 53–3 provide information about recommended chemoprophylactic and therapeutic dosage regimens involving chloroquine. Chloroquine and its analogues are also used to treat certain nonmalarial conditions, including hepatic amebiasis.
therapy should undergo ophthalmological and neurological evaluations every 3–6 months.

**Quinine and Quinidine**

Oral quinine is FDA-approved for the treatment of uncomplicated *P. falciparum* malaria. Quinidine, a stereoisomer of quinine, is more potent as an antimalarial and more toxic than quinine.

### Antimalarial Action and Resistance

Quinine acts against asexual erythrocytic forms and has no significant effect on hepatic forms of malarial parasites. This drug is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. Compared to artemisinin class therapy, quinine produces poorer clinical outcomes. However, quinine, along with its stereoisomer quinidine, is especially

*If used for presumptive self-treatment, medical care should be sought as soon as possible.

valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*. Because of its toxicity and short *t*½, quinine is generally not used for chemoprophylaxis. The antimalarial mechanism of quinine is presumably similar to that of chloroquine. The basis of *P. falciparum* resistance to quinine is complex. Patterns of *P. falciparum* resistance to quinine correlate in some strains with resistance to chloroquine yet in others correlate more closely with resistance to mefloquine and halofantrine. A number of transporter genes may confer resistance to quinine.

**Action on Skeletal Muscle.** Quinine not only increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. Quinine can antagonize the actions of physostigmine on skeletal muscle. Quinine may also produce alarming respiratory distress and dysphagia in patients with myasthenia gravis.

**ADME.** Quinine is readily absorbed when given orally or intramuscularly. Oral absorption occurs mainly from the upper small intestine and is more than 80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels reach a maximum in 3–8 h and, after distributing into an apparent volume of about 1.5 L/kg, decline with a *t*½ of about 11 h. The pharmacokinetics of quinine may change with severe malarial infection: The apparent volume of distribution and the systemic clearance of quinine decrease, such that the average elimination *t*½ increases to 18 h. The high levels of plasma α1-acid glycoprotein produced in severe malaria may prevent toxicity by binding quinine and thereby reducing the free fraction of drug. Concentrations of quinine in lower in erythrocytes (33%–40%) and CSF (2%–5%) than in plasma, and the drug readily reaches fetal tissues. The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4; thus, only about 20% of an administered dose is excreted in an unaltered form in the urine. The major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of quinine itself is more rapid when the urine is acidic.

**Therapeutic Uses.** Quinine and quinidine have long been treatments of choice for drug-resistant and severe *P. falciparum* malaria. However, the advent of oral and intravenous artesiminin therapy has changed this situation. Standard of care for severe illness, and only until artesiminin therapy can be started, is the prompt use of loading doses of intravenous quinine (or quinidine, where intravenous quinine is not available) can be lifesaving. Oral medication to maintain therapeutic concentrations is then given as soon as tolerated and is continued for 5–7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizonticides such as tetracyclines or clindamycin are given concurrently to enhance quinine efficacy. Formulations of quinine and quinidine and specific regimens for their use in the treatment of *P. falciparum* malaria are shown in the Drug Facts table.

The therapeutic range for “free” quinine is 0.2 and 2.0 mg/L. Regimens needed to achieve this target vary based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. Dosage regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger apparent volume of distribution, greater systemic clearance, and shorter terminal elimination *t*½ than quinine. The CDC recommends a dose of quinidine of 10 mg salt/kg initially, followed by 0.02 mg salt/kg/min.

**Nocturnal Leg Cramps.** It is commonly believed that night cramps are relieved by quinine (200–300 mg) taken at bedtime. The FDA has required drug manufacturers to stop marketing over-the-counter quinine products for nocturnal leg cramps, stating that data supporting safety and efficacy of quinine for this indication were inadequate and that risks outweighed the potential benefits.
Toxicity and Side Effects. The fatal oral dose of quinine for adults is about 2–8 g. Quinine is associated with a triad of dose-related toxicities when given at full therapeutic or excessive doses: cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism (consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension) occur frequently and disappear soon after the drug is withdrawn. Hypoglycemia is also common and can be life threatening if not treated promptly with intravenous glucose. Hypotension is rare and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and skin manifestations. GI symptoms (nausea, vomiting, abdominal pain, and diarrhea) result from the local irritant action of quinine, but the nausea and emesis also have a central basis. Cutaneous manifestations may include flushing, sweating, rash, and angioedema, especially of the face. Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells.

Quinine rarely causes cardiac complications unless therapeutic plasma concentrations are exceeded. QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. Acute overdose also may cause serious and even fatal cardiac dysrhythmias, such as sinus arrest, junctional rhythms, atrioventricular block, and ventricular tachycardia and fibrillation. Quinidine is even more cardiotoxic than quinine. Cardiac monitoring of patients on intravenous quinidine is advisable where possible. Severe hemolysis can result from hypersensitivity to these cinchona alkaloids. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and in some instances death—is a rare hypersensitivity reaction to quinine therapy that can occur during treatment of malaria. Quinine occasionally may cause milder hemolysis, especially in people with G6PD deficiency. Thrombotic thrombocytopenic purpura also is rare but can occur even in response to ingestion of tonic water, which has about 4% the therapeutic oral dose per 12 oz (“cocktail purpura”). Other rare adverse effects include hypoprothrombinemia, leukopenia, and agranulocytosis.

Research in model systems indicated that quinine can inhibit a number of transport proteins, including Tat2p, which transports tryptophan, the precursor of 5HT. Quinine also competitively inhibits the rate-limiting step in 5HT biosynthesis, tryptophan hydroxylase (Islahudin et al., 2014; Khozoie et al., 2009). Whether these data relate to adverse effects of quinine in humans remains to be determined.

Precautions, Contraindications, and Drug Interactions. Quinine must be used with considerable caution, if at all, in patients who manifest hypersensitivity. Quinine should be discontinued immediately if evidence of hemolysis appears. This drug should be avoided in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine. Quinine appears to be safe in pregnancy and is used commonly for the treatment of pregnancy-associated malaria. However, glucose levels must be monitored because of the increased risk of hypoglycemia.

Quinine and quinidine are highly irritating and should not be given subcutaneously. Concentrated solutions may cause abscesses when injected intramuscularly or thrombophlebitis when infused intravenously. Antacids that contain aluminum can delay absorption of quinine from the GI tract. Quinine and quinidine can delay the absorption and elevate plasma levels of cardiac glycosides and warfarin and related anticoagulants. The action of quinine at neuromuscular junctions enhances the effect of neuromuscular blocking agents and opposes the action of acetylcholinesterase inhibitors. Prochlorperazine can amplify quinidine’s cardiotoxicity, as can halofantrine. The renal clearance of quinine can be decreased by cimetidine and increased by urine acidification and by rifampin.

Mefloquine

Mefloquine emerged from the Walter Reed Malaria Research Program as safe and effective against drug-resistant strains of P. falciparum.

Mechanisms of Action and Resistance. Mefloquine is a highly effective blood schizonticide. Mefloquine associates with intraerythrocytic hemoglobin, suggesting similarities to the mode of action of chloroquine. However, increased pfmdr1 copy numbers are associated with both reduced parasite susceptibility to mefloquine and increased PfMDR1-mediated solute import into the digestive vacuole of intraerythrocytic parasites, suggesting that the drug’s target resides outside this vacuolar compartment. The (−)-enantiomer is associated with adverse CNS effects; the (+)-enantiomer retains antimalarial activity with fewer side effects. Mefloquine can be paired with artemesunate to reduce the selection pressure for resistance. This combination has proved efficacious for the treatment of P. falciparum malaria, even in regions with high prevalence of mefloquine-resistant parasites.

ADME. Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is absorbed rapidly but with marked variability. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of mefloquine rise in a biphasic manner to their peak in about 17 h. Mefloquine has a variable and long t½, 13–24 days, reflecting its high lipophilicity, extensive tissue distribution, and extensive binding (about 98%) to plasma proteins. The slow elimination of mefloquine fosters the emergence of drug-resistant parasites. Mefloquine is extensively metabolized in the liver by CYP3A4; this CYP can be inhibited by ketoconazole and induced by rifampin. Excretion of mefloquine is mainly by the fecal route; about 10% of mefloquine appears unchanged in the urine.

Therapeutic Uses. Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant P. falciparum and P. vivax; it is no longer considered first-line treatment of malaria. The drug is especially useful as a chemoprophylactic agent for travelers spending weeks to years in areas where these infections are endemic (see Table 53–2). In areas where malaria is due to multiply drug-resistant strains of P. falciparum, mefloquine is more effective when used in combination with an artemisinin compound.

Toxicity and Side Effects. At chemoprophylactic dosages, while oral mefloquine is generally well tolerated, the U.S. FDA has added a “black box” warning to mefloquine labeling, noting the drug’s potential to cause severe, possibly permanent, neurological and psychiatric adverse effects. Vivid dreams are common; significant neuropsychiatric signs and symptoms can occur in 10% or more of people receiving treatment doses; serious adverse events (psychosis, seizures) are rare. Short-term adverse effects of treatment include nausea, vomiting, and dizziness. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour. After treatment of malaria with mefloquine, CNS toxicity can be as high as 0.5%; symptoms include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms are reversible on drug discontinuation. Mild-to-moderate toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at prophylactic dosages. Adverse effects usually manifest after the first to third doses and often abate even with continued treatment. Cardiac abnormalities, hemolysis, and agranulocytosis are rare.

Contraindications and Drug Interactions. At very high doses, mefloquine is teratogenic in rodents. Studies have suggested an increased rate of stillbirths with mefloquine use, especially during the first trimester. Pregnancy should be avoided for 3 months after mefloquine use because of the prolonged t½ of this agent. This drug is contraindicated for patients with a history of seizures, depression, bipolar disorder and other severe neuropsychiatric conditions, or adverse reactions to quinoline antimalarials. Although this drug can be taken safely 12 h after a last dose of quinine, taking quinine shortly after mefloquine can be hazardous because the latter is eliminated so slowly. Treatment with or after halofantrine or within 2 months of prior mefloquine administration is contraindicated. Controlled studies suggest that mefloquine does not impair performance in persons who tolerate the drug; nonetheless, some advise against the use of mefloquine for patients in occupations that require focused concentration, dexterity, and cognitive function.
**Primaquine**

Primaquine, in contrast to other antimalarials, acts on exoerythrocytic tissue stages of *Plasmodium* spp. in the liver to prevent and cure relapsing malaria. Patients should be screened for G6PD deficiency prior to therapy with this drug.

**Antimalarial Action and Parasite Resistance.** The mechanism of action of the 8-aminoquinolines has not been elucidated. Primaquine acts against primary and latent hepatic stages of *Plasmodium* spp. and prevents relapses in *P. vivax* and *P. ovale* infections. This drug and other 8-aminoquinolines also display gametocidal activity against *P. falciparum* and other *Plasmodium* species. However, primaquine is inactive against asexual blood-stage parasites.

**Toxicity and Side Effects.** Primaquine has few side effects when given in the usual therapeutic doses. Primaquine can cause mild-to-moderate abdominal distress in some individuals. Taking the drug at mealtime often alleviates these symptoms. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60–240 mg daily) worsen the abdominal symptoms. Methemoglobinemia can occur even with usual doses of primaquine and can be severe in individuals with congenital deficiency of NADH methemoglobin reductase (NADH-cytochrome b5 reductase [diaphorase 1]). Chloroquine and dapsone may synergize with primaquine to produce methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Other rare adverse reactions are hypertension, arrhythmias, and symptoms referable to the CNS.

**Therapeutic Uses.** Primaquine is used primarily for terminal chemoprophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) infections because of its high activity against the latent tissue forms (hypnozoites) of these *Plasmodium* species. The compound is given together with a blood schizonticide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance. For terminal chemoprophylaxis, primaquine regimens should be initiated shortly before or immediately after a subject leaves an endemic area (see Table 53–2). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during an asymptomatic latent period of presumed infection or during an acute attack. Simultaneous administration of a schizonticidal drug plus primaquine is more effective than sequential treatment in promoting a radical cure. Limited studies demonstrated efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine was taken as chemoprophylaxis. Primaquine is generally well tolerated when taken for up to 1 year.

**Mechanism of Action**

Sulfonamides are p-aminobenzoic acid analogues that competitively inhibit *Plasmodium* dihydropteroate synthase. These agents are combined with an inhibitor of parasite dihydrofolate reductase to enhance their antimalarial action. See Figure 56–2 and neighboring text for details of these agents.

**Drug Resistance**

Sulfadoxine resistance is conferred by several point mutations in the dihydropteroate synthase gene. These sulfadoxine resistance mutations, when combined with mutations of dihydrofolate reductase and conferring pyrimethamine resistance, greatly increase the likelihood of sulfadoxine-pyrimethamine treatment failure. Sulfadoxine-pyrimethamine, given intermittently during the second and third trimesters of pregnancy, is a routine component of antenatal care throughout Africa. Intermittent preventive treatment strategies may also benefit infants. Generally, one can anticipate that, in the absence of novel antibiotics effective against existing drug-resistant strains, the use of these antimalarials for either prevention or treatment will continue to decline.

**Tetracyclines and Clindamycin**

Tetracycline and doxycycline are useful in malaria treatment, as is clindamycin. These agents are slow-acting blood schizonticides that are used alone for short-term chemoprophylaxis in areas with chloroquine- and mefloquine-resistant malaria (only doxycycline is recommended for malaria chemoprophylaxis).

These antibiotics act via a delayed-death mechanism resulting from their inhibition of protein translation in the parasite apicoplast.
(an organelle evolutionarily derived from plant chloroplasts). This effect on malarial parasites manifests as death of the progeny of drug-treated parasites, resulting in slow onset of antimalarial activity. Their relatively slow mode of action makes these drugs ineffective as single agents for malaria treatment. Dosage regimens for tetracyclines and clindamycin are listed in the Drug Facts table. Because of their adverse effects on bones and teeth, tetracyclines should not be given to pregnant women or to children younger than 8 years. For details of these agents, see Chapter 59.

### Principles and Guidelines for Chemoprophylaxis and Chemotherapy of Malaria

Pharmacological prevention of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Oral artemether-lumefantrine is likely appropriate as first-line antimalarial treatment of uncomplicated malaria. Chloroquine remains effective against malaria caused by *P. ovale*, *P. malariae*, and *P. knowlesi*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* are now the rule, not the exception, in most malaria-endemic regions (see Figure 53–1). Extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine-sulfadoxine. Multidrug-resistant *P. falciparum* malaria is especially prevalent and severe in Southeast Asia and Oceania. These infections may not respond adequately even to mefloquine or quinine. The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. Current CDC recommendations for drugs and dosing regimens for the chemoprophylaxis and treatment of malaria in nonimmune individuals are shown in Tables 53–2 and 53–3.

**Drugs should not replace simple, inexpensive measures for malaria prevention.** Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites. One such measure is to avoid exposure to mosquitoes at dusk and dawn, usually the times of maximal feeding. Others include using insect repellents containing at least 30% DEET and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin.

### Malaria Chemoprophylaxis

Regimens for malaria chemoprophylaxis include primarily three drugs: atovaquone-proguanil and doxycycline, which can both be used in all areas; and mefloquine, which can be used in areas with mefloquine-sensitive malaria. Other available options are chloroquine or hydroxychloroquine (but their use is restricted to the few areas with chloroquine-sensitive malaria) and primaquine (for short-duration travel to areas with predominantly *P. vivax*). In general, dosing should be started before exposure, ideally before the traveler leaves home (see Table 53–2).

In those few areas where chloroquine-resistant strains of *P. falciparum* are found, chloroquine is still suitable for chemoprophylaxis. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone-proguanil are the regimens of choice for chemoprophylaxis. For chemoprophylaxis in long-term travelers, chloroquine is safe at the doses used, but some recommend yearly retinal examinations, and there is a finite dose limit for which chemoprophylaxis with chloroquine is recommended because of ocular toxicity. Mefloquine and doxycycline are well tolerated. Mefloquine is the best-documented drug for malaria prophylaxis in long-term travelers and, if well tolerated, can be used for prolonged periods. Atovaquone-proguanil has been studied for prophylactic use up to 20 weeks but probably is acceptable for years based on experience with the individual components.

### Self-Treatment of Presumptive Malaria for Travelers

The CDC provides travelers’ guidelines for self-treatment of presumptive malaria with appropriate drugs (atovaquone-proguanil, artemether-lumefantrine; as described in Table 53–3) when professional care is not available within 24 h. In such cases, medical care should be sought immediately after treatment. These recommendations may change over time and with specific locations. Consult the CDC Yellow Book (https://wwwnc.cdc.gov/travel/page/yellowbook-home-2014).

### Diagnosis and Treatment of Malaria

The diagnosis of malaria must be considered for patients presenting with acute febrile illness after returning from a malaria-endemic region. An organized, rational approach to diagnosis, parasite identification, and appropriate treatment is crucial. Guidelines for treatment of malaria in the U.S. are provided by the CDC and are shown Figure 53–3, with details of the available agents summarized in Table 53–3. More information is available online (http://www.cdc.gov/malaria/resources/pdf/treatmenttable.pdf) and from the CDC Malaria Hotline (770-488-7788 and 770-488-7100).

Children and pregnant women are the most susceptible to severe malaria. The treatment of children generally is the same as for adults (pediatric dose should never exceed adult dose) (see the Drug Facts table). However, tetracyclines should not be given to children less than 8 years of age except in an emergency, and atovaquone-proguanil as treatment has been approved only for children weighing more than 5 kg.

### Chemoprophylaxis and Treatment During Pregnancy

Chemoprophylaxis during pregnancy is complex, and women should evaluate with expert medical staff the benefits and risks of different strategies with regard to their particular situations. Severe malaria during pregnancy should be treated with intravenous antimalarial treatment according to the general guidelines for severe malaria, taking into account the drugs that should be avoided during pregnancy. In lactating mothers, treatment with most compounds is acceptable, although chloroquine and hydroxychloroquine are the preferred agents. The use of atovaquone-proguanil is not recommended unless breastfeeding infants weigh more than 5 kg. Also, the breastfeeding infant should be shown to have a normal G6PD level before receiving primaquine.

### Treating the Mosquito Rather Than the Human

Recent technological developments seem likely to revolutionize mosquito control and mosquito susceptibility to malarial parasites. Isaacs et al. (2011) engineered resistance to infection by *P. falciparum* in mosquitoes by having the mosquitoes express single-chain antibodies that targeted antigens on the parasite’s surface and inhibited the parasite’s capacity to invade the midgut and salivary glands of the mosquito, effects that would reduce or eliminate the capacity of the mosquito to infect humans in the course of a blood meal.

The development of gene editing using CRISPR/cas9 (see Chapter 3) has opened up a new avenue for high-efficiency expression of resistance genes for treating the spread and prevalence of malaria. Gantz and Bier (2015) have described a “mutagenic chain reaction” based on CRISPR/cas9 that can spread a mutation from one chromosome to its homologous chromosome in mosquitoes. Other CRISPR/cas9 endonuclease constructs have driven genes in the malarial vector *Anopheles gambiae* to the midgut and salivary glands of the mosquito, effects that would reduce or eliminate the capacity of the mosquito to infect humans in the course of a blood meal.

The development of gene editing using CRISPR/cas9 has opened up a new avenue for high-efficiency expression of resistance genes for treating the spread and prevalence of malaria. Gantz and Bier (2015) have described a “mutagenic chain reaction” based on CRISPR/cas9 that can spread a mutation from one chromosome to its homologous chromosome in mosquitoes. Other CRISPR/cas9 endonuclease constructs have driven genes in the malarial vector *Anopheles gambiae* to the midgut and salivary glands of the mosquito, effects that would reduce or eliminate the capacity of the mosquito to infect humans in the course of a blood meal.

It seems likely that this gene editing–gene drive technology will be applicable to other vector-borne diseases. As Hammond et al. (2016) noted, “The success of gene drive technology for vector control will depend on the choice of suitable promoters to effectively drive homing during ... gametogenesis, the phenotype of the disrupted genes, the robustness of the nuclease during homing and the ability of the target population to generate compensatory mutations.” CRISPR/cas9 gene drives have not yet been released into the wild. Indeed, the use of these techniques in the field must be approached with caution and must await a full understanding of the ecological consequences and the ethical and regulatory issues.
Perform thick and thin blood films and read within a few hours

History of travel to malaria-endemic area or clinical suspicion of malaria

Yes, Blood film positive?

Repeat blood films every 12 to 24 h for a total of 3 sets

No, Blood film positive?

Calculate parasitemia

Consider alternate diagnoses

Evaluate clinical status and disease severity

Uncomplicated malaria

Determine species

Plasmodium falciparum or species not yet identified

P. vivax acquired outside Papua New Guinea or Indonesia

Plasmodium ovale or P. vivax acquired in Papua New Guinea or Indonesia

Non-falciparum species

Acquired in chloroquine-sensitive area

Acquired in chloroquine-resistant area

Acquired in mefloquine-resistant area

Atovaquone-proguanil or Artemether-lumefantrine or Quinine plus tetracycline or doxycycline or clindamycin

Atovaquone-proguanil or Mefloquine

Chloroquine or Hydroxychloroquine

Atovaquone-proguanil or Quinine plus tetracycline or doxycycline or Methloquine

P. malariae

P. ovale or P. vivax acquired outside Papua New Guinea or Indonesia

P. knowlesi

Plasmodium falciparum or species not yet identified

Chloroquine or Hydroxychloroquine

Atovaquone-proguanil or Artemether-lumefantrine or Quinine plus tetracycline or doxycycline or clindamycin

Intravenous quinidine plus tetracycline, or doxycycline, or clindamycin

If quinidine is unavailable contact CDC malaria hotline for artesunate

Admit to hospital to monitor for progression of disease severity

Admit to intensive care unit for continuous cardiac monitoring. Prevent and treat complications.

Switch to oral medicines to complete the treatment regimen after appropriate clinical response

Repeat blood films if symptoms recur

Primaquine if not G6PD deficient

<td><strong>Artemether-lumefantrine</strong>&lt;br&gt; <em>P. falciparum</em> from chloroquine-resistant or unknown areas</td>
<td>Tablet: 20 mg artemether, lumefantrine. Dose: 4 tablets. Day 1: 2 doses separated by 8 h; thereafter twice daily × 2 days</td>
<td>Wgt (kg) ≤ 15 15–25 25–&lt;35 &gt;35&lt;br&gt;Tablets/dose 2 3 4</td>
<td>Adults; headache anorexia, dizziness, asthenia, arthralgia myalgia&lt;br&gt;Children: fever, cough, vomiting, loss of appetite, headache</td>
<td>Take with food or whole milk. If patient vomits within 30 min, repeat dose. Contraindicated in pregnancy.</td>
</tr>
<tr>
<td><strong>Artesunate</strong>&lt;br&gt; (IV; available from CDC) Severe malaria; see CDC guidelines.</td>
<td>U.S. treatment IND (CDC): 4 equal doses of artesunate (2.4 mg/kg each) over a 3-day period followed by oral treatment with atovaquone-proguanil, doxycycline, clindamycin, or mefloquine (to avoid emergence of resistance)</td>
<td>See Artemether</td>
<td>See Artemether CDC guidelines</td>
<td></td>
</tr>
<tr>
<td><strong>Atovaquone-proguanil</strong>&lt;br&gt; <em>P. falciparum</em> from chloroquine-resistant areas&lt;br&gt; <em>P. vivax</em></td>
<td>Adult tablet 250 mg atovaquone/100 mg proguanil. 4 adult tablets orally per day × 3 days</td>
<td>Pediatric tablet = 62.5 mg atovaquone/25 mg proguanil&lt;br&gt;5–8 kg: 2 ped tab orally/d × 3 d&lt;br&gt; &gt;8–10 kg: 3 ped tab daily × 3 d&lt;br&gt; &gt;10–20 kg: 1 adult tab daily × 3 d&lt;br&gt; &gt;20–30 kg: 2 adult tab daily × 3 d&lt;br&gt; &gt;30–40 kg: 3 adult tab daily × 3 d&lt;br&gt; &gt;40 kg: 4 adult tab daily × 3 d</td>
<td>Abdominal pain, nausea, vomiting, diarrhea, headache, rash, mild reversible elevations in liver aminotransferase levels</td>
<td>Not indicated for use in pregnant women due to limited data. Contraindicated if hypersensitivity to atovaquone or proguanil; severe renal impairment (creatinine clearance &lt; 30 mL/min). Should be taken with food to increase absorption of atovaquone.</td>
</tr>
<tr>
<td><strong>Chloroquine phosphate</strong>&lt;br&gt; <em>P. falciparum</em> from chloroquine-sensitive areas&lt;br&gt; *P. vivax&lt;br&gt; *P. ovale&lt;br&gt; *P. knowlesi&lt;br&gt; *P. malariae&lt;br&gt; <em>P. knowlesi</em></td>
<td>600 mg base (1000 mg salt) orally immediately, followed by 300 mg base (500 mg salt) orally at 6, 24, and 48 h Total dose: 1500 mg base (2500 mg salt)</td>
<td>10 mg base/kg orally immediately, followed by 5 mg base/kg orally at 6, 24, and 48 h Total dose: 25 mg base/kg</td>
<td>Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus</td>
<td>Safe in children and pregnant women. Give for chemoprophylaxis (500 mg salt orally every day) in pregnant women with chloroquine-sensitive <em>P. vivax</em>. Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines. Use with caution in those with impaired liver function since the drug is concentrated in the liver.</td>
</tr>
<tr>
<td><strong>Clindamycin</strong> (oral or IV)&lt;br&gt; <em>P. falciparum</em> from chloroquine-resistant areas&lt;br&gt; <em>P. vivax</em> from chloroquine-resistant areas</td>
<td>Oral: 20 mg base/kg orally divided 3 times daily × 7 d&lt;br&gt; IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral meds; duration = 7 d</td>
<td>Oral: 20 mg base/kg orally divided 3 times daily × 7 d&lt;br&gt; IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication; treatment course = 7 d</td>
<td>Diarrhea, nausea, rash</td>
<td>Always use in combination with quinine-quinidine. Safe in children and pregnant women.</td>
</tr>
<tr>
<td><strong>Doxycycline</strong> (oral or IV)&lt;br&gt; <em>P. falciparum</em> and <em>P. vivax</em> from chloroquine-resistant areas</td>
<td>Oral: 100 mg orally twice daily × 7 d. IV: 100 mg IV every 12 h and then switch to oral doxycycline (as above) as soon as patient can take oral medication; treatment course = 7 d.</td>
<td>Oral: 2.2 mg/kg orally every 12 h × 7 d. IV: Only if patient is not able to take oral medication; for children &lt; 45 kg, give 2.2 mg/kg IV every 12 h and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication; for children &gt; 45 kg, use same dosing as for adults; duration = 7 d.</td>
<td>Nausea, vomiting, diarrhea, abdominal pain, dizziness, photosensitivity, headache, esophagitis, odynophagia. Rarely hepatotoxicity, pancreatitis, and benign intracranial hypertension seen with tetracycline class of drugs.</td>
<td>Always use in combination with quinine or quinidine. Contraindicated in children &lt; 8 y, pregnant women, and persons with known hypersensitivity to tetracyclines. Food, milk, and Ca2+ antacids decrease absorption and decrease GI disturbances. To prevent esophagitis, take tetracyclines with large amounts of fluids (patients should not lie down for 1 h after taking the drugs). Barbiturates, carbamazepine, or phenytoin may cause reduction in Cmax of doxycycline.</td>

These regimens are based on published recommendations of the U.S. CDC. Although current at the time of writing, these recommendations may change over time. Up-to-date information should be obtained from the CDC website at https://wwwnc.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the last, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

Pediatric dosage should never exceed adult dosage.

†Extrapolated from chloroquine literature.

‡Mefloquine should not be used to treat P. falciparum infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

§Quinine sulfate capsule manufactured in the U.S. is in a 324-mg dose; therefore, 2 capsules should be sufficient for adult dosing.

âNausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

bRefer to quinine sulfate, package insert (Mutual Pharmaceutical Inc., Philadelphia, PA, Rev. 08, November 2009).

cAlternative dosing hypoglycemia optic neuritis regimen for quinidine gluconate (IV): 15 mg base/kg (24 mg salt/kg) loading dose IV infused over 4 h, followed by 7.5 mg base/kg (≈ 12 mg salt/kg) infused over 4 h every 8 h, starting 8 h after the loading dose (see package insert); once parasite density < 1% and patient can take oral medication, complete treatment with oral quinine, dose as above. Quinidine or quinine course = 7 d in Southeast Asia (3 d in Africa or South America).

dRefer to quinidine gluconate, package insert (Eli Lilly Co., Indianapolis, IN, February 2002).

Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections

Dawn M. Wetzel and Margaret A. Phillips

Protozoal Infections of Humans

Amebiasis

Amebiasis affects about 10% of the world’s population, causing invasive disease in about 50 million people and death in about 100,000 of these annually (Stanley, 2003). Amebiasis is seen most commonly among individuals living in poverty, crowded conditions, and areas with poor sanitation (Petri, 2014). Three morphologically identical but genetically distinct species of Entamoeba—E. histolytica, E. dispar, and E. moshkovskii—exist (Petri, 2014). In addition, Entamoeba bangladeshi was recently discovered in diarrheal samples and may be pathogenic (Royer et al., 2012). However, the major species that definitely requires treatment is E. histolytica, the third-leading cause of mortality by parasitic infection.

Humans are the only known hosts for these protozoa, which are transmitted by the fecal–oral route. Ingested E. histolytica cysts survive acid gastric contents and transform into trophozoites that reside in the large intestine (Petri, 2014). The outcome of E. histolytica infection is variable. Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals, E. histolytica trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). In a small proportion of patients, E. histolytica trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess (Haque et al., 2003). Both host and parasite factors influence the course and severity of the disease (Marie and Petri, 2014).

The cornerstone of therapy for amebiasis is metronidazole or its analogue tinidazole (Haque et al., 2003; Petri, 2014; Stanley, 2003). Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen. The drug is also less effective against cysts. Therefore, patients with amebic colitis or amebic liver abscess should receive a luminal agent in addition to metronidazole to eradicate any E. histolytica trophozoites residing within the gut lumen. Luminal agents are also used to treat asymptomatic individuals found to be infected with E. histolytica. The nonabsorbed aminoglycoside paromomycin and the 8-hydroxyquinoline compound iodoquinol are effective luminal agents (Haque et al., 2003). In addition, nitazoxanide, which is approved in the U.S. for treatment of cryptosporidiosis and giardiasis, has activity against E. histolytica (Adagu et al., 2002).

Giardiasis

Giardiasis, caused by the flagellated protozoa Giardia intestinalis, is prevalent worldwide and is the most commonly reported intestinal protozoal infection in the U.S. Infection results from ingestion of the cyst form of the parasite, which is found in fecally contaminated water or food. Cysts shed from animals or infected humans can contaminate recreational and drinking water supplies (Fletcher et al., 2012). Human-to-human transmission is common among children in day-care centers, institutionalized individuals, and male homosexuals (Escobedo, Almirall, et al., 2014). Infection with Giardia results in one of three syndromes:

- an asymptomatic carrier state
- acute self-limited diarrhea
- chronic diarrhea, characterized by signs of malabsorption (steatorrhea) and weight loss
Toxoplasmosis is a zoonotic infection caused by the obligate intracellular protozoan Toxoplasma gondii. Although cats and other feline species are the natural hosts, tissue cysts (bradyzoites) have been recovered from all mammalian species examined. Common routes of infection in humans are as follows:

- ingestion of undercooked meat containing tissue cysts;
- ingestion of contaminated vegetable matter containing infective oocysts;
- direct oral contact with feces of cats shedding oocysts; or
- transplacental fetal infection with tachyzoites from acutely infected mothers (Woodhall et al., 2014).

The acute illness is usually self-limiting, and treatment rarely is required. However, individuals who are immunocompromised, such as patients with AIDS, are at risk of developing toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain (Jones et al., 2014). Clinical manifestations of congenital toxoplasmosis vary, but chorioretinitis, which may present decades after exposure, is the most common finding (Kieffer and Wallon, 2013).

The primary treatment of toxoplasmic encephalitis consists of the antifolates pyrimethamine and sulfadiazine along with folinic acid (leucovorin) (Woodhall et al., 2014). Therapy must be discontinued in about 40% of cases because of toxicity, primarily due to the sulfon compound (Yan et al., 2013). Pyrimethamine-clindamycin appears to have comparable efficacy to pyrimethamine-sulfadiazine for treating toxoplasmosis in immunocompromised patients, but this combination also causes substantial toxicity (Rajakapakse et al., 2013). Alternative regimens combining azithromycin, clarithromycin, atovaquone, or dapsone with either trimethoprim-sulfamethoxazole or pyrimethamine are not only less toxic but also less effective (Rajakapakse et al., 2013). Spiramycin, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in early pregnancy to prevent transmission to the fetus (Kieffer and Wallon, 2013). Spiramycin is available through the investigational new drug process at the U.S. FDA. If fetal infection occurs, the combination of pyrimethamine, sulfadiazine, and folinic acid is administered to the mother (only after the first 12–14 weeks of pregnancy) and to the newborn postnatally for 1 year (Contopoulos-Ioannidis and Montoya, 2012; Kieffer and Wallon, 2013).

Cryptosporidiosis

Cryptosporidia are coccidian protozoan parasites that cause diarrhea. Cryptosporidium parvum and the newly named Cryptosporidium hominis appear to account for almost all infections in humans (Checkley et al., 2015). Infectious oocysts in feces may be spread either by direct human-to-human contact or by contaminated water supplies. Groups at risk include travelers, children in day care, male homosexuals, animal handlers, and veterinary or healthcare personnel. After ingestion, the mature oocyte is digested, releasing sporozoites that invade epithelial cells (Wilhelm and Yarovinsky, 2014). In most individuals, infection is self-limited. However, in patients with AIDS and other immunocompromised individuals, the severity of diarrhea may require hospitalization (Marcos and Gotuzzo, 2013).

Nitazoxanide has shown activity in treating cryptosporidiosis in immunocompetent children and adults (White, 2014). Its efficacy in children and adults with HIV/AIDS or other immunocompromising conditions is not clearly established (Cabada and White, 2010). The most effective therapy for cryptosporidiosis in immunocompromised patients is restoration of immune function (e.g., through HAART in patients with AIDS) (White, 2014).

Trypanosomiasis

African trypanosomiasis, or “sleeping sickness,” is caused by subspecies of the hemoflagellate Trypanosoma brucei that are transmitted by bloodsucking tsetse flies of the genus Glossina (Kennedy, 2013). Largely restricted to sub-Saharan Africa, the infection causes serious human illness and also threatens livestock (nagana), leading to protein malnutrition. In humans, the infection is fatal unless treated. Sleeping sickness is found in 36 countries in Africa, but the caseload has dropped significantly due to renewed control efforts, and fewer than 10,000 cases were reported in 2013 (WHO, 2015a).

The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream or lymph without CNS involvement (stage 1); stage 2 disease is characterized by CNS involvement (Kennedy, 2013). Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocardiitis that result from systemic dissemination of the parasites. There are two types of African trypanosomiasis: The East African (Rhodesian; T. brucei rhodesiense) variety produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and frequent terminal cardiac failure; the West African type (Gambian; T. brucei gambiense) causes illness characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion,
sensory deficits, psychiatric signs, disruption of the sleep cycle, and eventual progression into coma and death.

Standard therapy for early-stage disease is pentamidine for T. brucei gambiense and suramin for T. brucei rhodesiense (Barrett et al., 2007; Kennedy, 2013). Both compounds are given parenterally over long periods and are not effective against late-stage disease. The CNS phase was traditionally treated with melarsoprol (available from the CDC), a highly toxic agent that causes a fatal reactive encephalopathy in 2%–10% of treated patients. Eflornithine (available from the CDC), an inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism, is the only agent for the treatment of late-stage disease. It has efficacy against both early and late stages of human T. brucei gambiense infection; however, it is thought to be ineffective as monotherapy for infections of T. brucei rhodesiense. Notably, eflornithine has significantly fewer side effects than melarsoprol and is more effective than melarsoprol for treatment of late-stage Gambian trypanosomiasis. NECT (nifurtimox–eflornithine combination) allows shorter exposure to eflornithine with good efficacy and a reduction in adverse events; it has become the treatment of choice for late-stage T. brucei gambiense (Luţe et al., 2013; Yun et al., 2010). However, NECT is difficult to administer in a rural setting, and the lack of an alternative to melarsoprol to treat T. brucei rhodesiense is concerning. Two new orally available agents are currently in clinical trials, fexinidazole and SCYX-7158, which offer the potential for improved treatment of the disease if they successfully make it to registration (Eperon et al., 2014).

American trypanosomiasis, or Chagas disease, is a zoonotic infection caused by Trypanosoma cruzi (Bern et al., 2011; Chatelain, 2015; Messenger et al., 2015). The World Health Organization estimates that Chagas affects about 6–7 million worldwide. The spread of Chagas disease is primarily confined to Latin America, but due to immigration, a number of cases are now seen outside that region. Bloodsucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission may also occur. Within the Western Hemisphere, the United States has the seventh-highest caseload (300,000 identified cases), representing a significant public health concern because the parasite can also be transmitted by blood transfusion and organ transplantation (Bern et al., 2011; Hotze et al., 2013; Malik et al., 2015). Most cases in the U.S. arise through immigration, but the parasite and its vector are endemic in the southern half of the U.S. (Bern et al., 2011), and transmission within the U.S. can occur, as highlighted by five recent case reports from Texas (Garcia et al., 2015).

While the blood supply is now being monitored, lack of awareness of the disease can lead to nonoptimal care of those infected (Hotze et al., 2013). The clinical outcome of an infected patient can vary widely from asymptomatic to severe disease; whether genetic differences in T. cruzi isolates contribute to outcome is not firmly established (Kapliniski et al., 2015). The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megagastro, and death. Chagas heart disease is typically managed in accordance with American College of Cardiology/American Heart Association guidelines for treatment of heart failure, although whether doses of angiotensin-converting enzyme inhibitors and β adrenergic blockers should be adjusted downward is debated (Botoni et al., 2015). Most cases in the U.S. arise through immigration, but the parasite and its vector are endemic in the southern half of the U.S. (Bern et al., 2011), and transmission within the U.S. can occur, as highlighted by five recent case reports from Texas (Garcia et al., 2015).

While the blood supply is now being monitored, lack of awareness of the disease can lead to nonoptimal care of those infected (Hotze et al., 2013). The clinical outcome of an infected patient can vary widely from asymptomatic to severe disease; whether genetic differences in T. cruzi isolates contribute to outcome is not firmly established (Kapliniski et al., 2015). The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megagastro, and death. Chagas heart disease is typically managed in accordance with American College of Cardiology/American Heart Association guidelines for treatment of heart failure, although whether doses of angiotensin-converting enzyme inhibitors and β adrenergic blockers should be adjusted downward is debated (Botoni et al., 2013; Malik et al., 2015; Ribeiro et al., 2012). Atypical clinical presentations and higher morbidity have been observed in immunosuppressed or compromised patients.

Two nitroheterocyclic drugs, nifurtimox and benznidazole (both available from the CDC), are used to treat this infection, although neither is approved by the U.S. FDA. Both agents suppress parasitemia and can cure the acute phase of Chagas disease. Treatment of intermediate- and late-stage disease is likely also beneficial, although the usefulness of treating at these stages is still debated. Both nifurtimox and benznidazole are toxic and must be taken for long periods. Increased awareness among physicians, better drugs, and better diagnostic methods are badly needed to help combat this disease.

Leishmaniasis

Leishmaniasis is a complex vector-borne zoonosis caused by about 20 different species of intramacrophage protozoa of the genus Leishmania. Small mammals and canines generally serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of female phlebotomine sandflies (WHO, 2015b).

Various forms of leishmaniasis affect people in southern Europe and many tropical and subtropical regions throughout the world. Flagellated extracellular free promastigotes, regurgitated by feeding flies, enter the host, where they attach to and become phagocytized by tissue macrophages. These transform into amastigotes, which reside and multiply within phagolysosomes until the cell bursts. Released amastigotes then propagate the infection by invading more macrophages. Amastigotes taken up by feeding sandflies transform back into promastigotes, thereby completing the transformation cycle. The particular localized or systemic disease syndrome caused by Leishmania depends on the species or subspecies of infecting parasite, the distribution of infected macrophages, and especially the host’s immune response.

In increasing order of systemic involvement and clinical severity, major syndromes of human leishmaniasis are classified into cutaneous, mucocutaneous, diffuse cutaneous, and visceral (kala azar) forms (WHO, 2015b). The disease syndrome manifested depends on the species of infecting parasite, the distribution of infected macrophages, and the host immune response (Podinovskaia and Descoteaux, 2015). As such, leishmaniasis is increasingly recognized as an AIDS-associated opportunistic infection (van Griensven et al., 2014). Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring 3–18 months after infection, but can leave disfiguring scars (Monge-Maillo and Lopez-Velez, 2013). Mucocutaneous, diffuse cutaneous, and visceral leishmaniasis do not resolve without therapy. Visceral disease caused by Leishmania donovani is fatal unless treated (Sundar and Chakravarty, 2015).

The classic therapy for all species of Leishmania is with pentavalent antimony compounds such as sodium stibogluconate (sodium antimonyl gluconate); resistance is widespread, particularly in India (Sundar and Chakravarty, 2015). Recently, treatment of leishmaniasis has undergone major changes owing to the success of the first orally active agent, miltefosine, which has been FDA-approved for cutaneous, mucocutaneous, and visceral disease (Miltefosine (Impavido) for Leishmaniasis, 2014). Miltefosine also appears to have promise for treating dogs, an important animal reservoir of the disease (Alvar et al., 2006). However, its teratogenic effects limit its utility in women of childbearing age (Sindermann and Engel, 2006). As an alternative, liposomal amphotericin B is a highly effective agent for visceral leishmaniasis (Magill, 2014) and is now recommended therapy in the U.S. in a recently released treatment guideline (Aronson et al., 2016). In addition, paromomycin has been used with some success as a parenteral agent for visceral disease, and topical formulations of paromomycin have also been used for cutaneous disease (Monge-Maillo and Lopez-Velez, 2013).

Other Protozoal Infections

Just a few of the many less-common protozoal infections of humans are highlighted in this section.

Babesiosis

Babesiosis, caused by either Babesia microti or B. divergens, is a tick-borne zoonosis that superficially resembles malaria in that the parasites invade erythrocytes and produce a febrile illness, hemolysis, and hemoglobinuria. Although this infection usually is mild and self-limiting, it can be severe or even fatal in asplenic or severely immunocompromised individuals. Therapy is with a combination of clindamycin and quinine for severe disease or the combination of azithromycin and atovaquone for mild or moderate infections (Gelfand and Vannier, 2014; Vannier et al., 2015).

Balantidiasis

Balantidiasis, caused by the ciliated protozoan Balantidium coli, is an infection of the large intestine that may be confused with amebiasis. However, unlike amebiasis, this infection usually responds to tetracycline therapy (Schuster and Ramirez-Avila, 2008; Suh et al., 2014).

Other Coccidia

Cyclospora cayetanensis (S zumowski and Troemel, 2015) causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in immunocompromised individuals. Cyclospora cayetanensis, formerly known as...
as *Isospora belli*, causes diarrhea in patients with AIDS. Both *Cyclospora* and *Cystoisospora* respond to trimethoprim-sulfamethoxazole (Legua and Seas, 2013; Suh et al., 2014).

**Microsporidia**

Microsporidia are spore-forming, unicellular, eukaryotic organisms that were once thought to be parasites but are now classified as fungi (Field and Milner, 2015). As such, they are discussed in Chapter 61 (on antifungal agents).

### Antiprotozoal Drugs

For ease of reference, the myriad agents used to treat nonmalarial protozoal diseases are presented alphabetically.

**Amphotericin B**

The pharmacology, formulation, and toxicology of amphotericin B are presented in Chapter 61.

**Antiprotozoal Effects**

Amphotericin B is a highly effective antileishmanial agent that cures more than 90% of the cases of visceral leishmaniasis and is the drug of choice for antimonial-resistant cases (Mohamed-Ahmed et al., 2012). It is the recommended agent for visceral leishmaniasis in the U.S. (Aronson et al., 2016). Amphotericin B is also therapy for cutaneous or mucosal leishmaniasis and is effective for treating immunocompromised patients (van Griensven et al., 2014). Lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions (Bern et al., 2006).

**Mechanism of Action**

Amphotericin’s activity against *Leishmania* is similar to its antifungal effects (see Chapter 61). Amphotericin complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell. *Leishmania* has similar sterol composition to fungi, and amphotericin binds fungal sterols preferentially over host cholesterol (Moen et al., 2009).

**Therapeutic Uses**

Typical regimens of 10–20 mg/kg total dose given in divided doses over 10–20 days by intravenous infusion have yielded cure rates of more than 95%. In the U.S., the FDA recommends 3 mg/kg intravenously on days 1–5, 14, and 21 for a total dose of 21 mg/kg to treat visceral leishmaniasis or 3 mg/g/kg for 7–10 days to treat cutaneous disease. Shorter courses of the drug for treatment of visceral leishmaniasis have demonstrated good efficacy and provide a potential cost-saving alternative, although only a limited number of patients have been tested (Monge-Maillo and Lopez-Velez, 2013). In addition, combining antileishmanial drugs may be effective; further studies are needed for such regimens (Sundar and Chakravarty, 2013).

**Eflornithine**

Eflornithine (DFMO) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first and rate-limiting step in the biosynthesis of polyamines (putrescine, spermidine, and spermine) that are required for cell division and for normal cell differentiation (Jacobs et al., 2011). In trypanosomiasis, spermidine is required for the synthesis of trypanothione, a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite. Eflornithine is transported into the cell via an amino acid transporter (Tb AAT6) (Vincent et al., 2010).

Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion (Jacobs et al., 2011). The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity.

**Antitrypanosomal Effects**

Eflornithine is a cystostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion (Jacobs et al., 2011). The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity.

**ADME**

Eflornithine is given by intravenous infusion. The drug does not bind to plasma proteins but is well distributed and penetrates into the CSF, where estimated concentrations of at least 50 μM must be reached for parasite clearance (Burri and Brun, 2003). The mean t1/2 is 3–4 h, and renal clearance after intravenous administration is rapid (2 mL/min/kg), with more than 80% of the drug cleared by the kidney largely in unchanged form (Sanderson et al., 2008).

**Therapeutic Uses**

Eflornithine in combination with nifurtimox (NECT) is used for the treatment of late-stage West African trypanosomiasis caused by *T. brucei gamiense*. The combination is logistically easier to administer and better tolerated than eflornithine alone. Importantly, compared to eflornithine alone, NECT achieves a higher cure rate (96.5% vs. 91.5%). Dosing is as follows: 200 mg/kg IV every 12 h by 2-h infusion for 7 days plus nifurtimox (orally at 15 mg/kg/d in three divided doses [every 8 h]) for 10 days (Priotto et al., 2009).

**Toxicity and Side Effects**

Eflornithine causes adverse reactions that are generally reversible on withdrawal of the drug. Abdominal pain and headache are the predominant complaints, followed by reactions at the injection sites. Tissue infections and pneumonia are also observed. The most severe reactions for eflornithine alone were reported to include fever peaks (6%), seizures (4%), and diarrhea (2%) (Balasegaram et al., 2009; Priotto et al., 2008). For NECT, severe adverse events were reduced compared to eflornithine alone (14% vs. 29%), and treatment-related deaths were also fewer (0.7% vs. 2%) (Priotto et al., 2009). The case fatality rate for eflornithine (0.7%–1.2%) and for NECT (0.2%) is significantly lower than for melarsoprol (4.9%), and overall either eflornithine alone or NECT is superior to melarsoprol with respect to both safety and efficacy. Reversible hearing loss can occur after prolonged therapy with oral doses. Therapeutic doses of eflornithine are large and require coadministration of substantial volumes of intravenous fluid. This poses significant practical limitations in remote settings and can cause fluid overload in susceptible patients.

**8-Hydroxyquinolines**

The halogenated 8-hydroxyquinolines iodoquinol (diiodohydroxyquin) and cloquinol (iodochlorhydroxyquin) can be used as luminal agents to eliminate intestinal colonization with *E. histolytica* and combined with metronidazole to treat amebic colitis or amebic liver abscess. Because of its superior adverse-event profile, paromomycin is preferred as the luminal agent for amebiasis. However, iodoquinol, the safer of the two 8-hydroxyquinolines, is available for use in the U.S. and is a reasonable alternative. When used at appropriate doses (never to exceed 2 g/d) for short periods of time (not greater than 20 days in adults), adverse effects are unusual (Haque et al., 2003). However, using these drugs at high doses for long periods carries significant risk. The most important toxic reaction, ascribed primarily to cloquinol, is subacute myelo-optic
neuropathy (Meade, 1975). Administering iodoquinol in high doses to children with chronic diarrhea is associated with optic atrophy and permanent vision loss (Escobedo et al., 2009). Peripheral neuropathy is a less-severe manifestation of neurotoxicity from these drugs (Haque et al., 2003). For adults, the recommended dose of iodoquinol is 650 mg orally three times daily for 20 days, whereas children receive 30–40 mg/kg body weight orally, divided three times a day (not to exceed 1.95 g/d) for 20 days (Drugs for Parasitic Infections, 2013).

**Melarsoprol**

Despite the fact that it causes an often-fatal encephalopathy in 2%–10% of the patients treated with it, melarsoprol is the only drug for the treatment of late (CNS) stages of East African trypanosomiasis caused by *T. brucei rhodesiense* (Kennedy, 2013). Although melarsoprol is also effective against late-stage West African trypanosomiasis caused by *T. brucei gambiense*, NECT has become the first-line treatment of this disease.

Melarsoprol is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

**Mechanism of Action: Antiprotozoal Effects**

Melarsoprol is metabolized to melarsen oxide, the active drug (Barrett et al., 2007). Arsenoxides react avidly and reversibly with vicinal sulfhydryl groups and thereby inactivate many enzymes. Melarsoprol reacts with trypanothione, the spermidine-glutathione adduct that substitutes for glutathione in these parasites. Binding of melarsoprol to trypanothione results in a melarsen oxide–trypanothione adduct that inhibits trypanothione reductase. Treatment failure owing to resistance of trypanosomes to melarsoprol has risen sharply, and some of the resistant strains are an order of magnitude less sensitive to the drug. Resistance to melarsoprol arises due to transport defects linked to the aquaglyceroporin pore-forming protein (Munday et al., 2015).

**ADME**

Melarsoprol is always administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. Melarsoprol is a prodrug and is metabolized rapidly (<30 min) to melarsen oxide, the active form of the drug (Barrett et al., 2007). Bioassays show that the active metabolite has a terminal t1/2 of 43 h. A small but therapeutically significant amount of the drug enters the CSF and clears trypanosomes infecting the CNS.

**Therapeutic Uses**

Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis, which is nearly 100% fatal if untreated (Kennedy, 2013). The drug is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. Patients infected with *T. brucei rhodesiense* who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with *T. brucei gambiense* who are not cured with melarsoprol rarely benefit from repeated treatment with this drug. Such patients often respond well to eflornithine.

Dosing is 2.2 mg/kg/d IV for 10 days for both *T. brucei gambiense* (Pepin and Mpia, 2006) and *T. brucei rhodesiense* (Kuepfer et al., 2012).

ENCEPHALOPATHY develops more frequently in patients with *T. brucei rhodesiense* compared to *T. brucei gambiense*. Concurrent administration of prednisolone is frequently employed throughout the treatment course to reduce the prevalence of encephalopathy.

**Toxicity and Side Effects**

Treatment with melarsoprol is associated with significant toxicity and morbidity (Barrett et al., 2007; Kennedy, 2013). A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs 9–11 days after treatment starts in about 5%–10% of patients, leading to death in about half of these. Peripheral neuropathy occurs in about 10% of patients receiving melarsoprol. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and evidence of renal or hepatic damage may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting melarsoprol slowly into the supine, fasting patient.

**Precautions and Contraindications**

Melarsoprol should be given only to patients under hospital supervision. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprous patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. The drug may be used in pregnancy.

**Metronidazole and Tinidazole**

Metronidazole is active in vitro against a wide variety of anaerobic protozoal parasites and anaerobic bacteria. Other clinically effective 5-nitroimidazoles closely related in structure and activity to metronidazole include tinidazole, secnidazole, and ornidazole. Among these, only tinidazole is available in the U.S. Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis. Metronidazole manifests antibacterial activity against all anaerobic cocci; anaerobic gram-negative bacilli, including *Bacteroides* spp.; anaerobic spore-forming, gram-positive bacilli such as *Clostridium*; and microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria (Lofmark et al., 2010). Please refer to Chapter 59 on protein synthesis inhibitors for additional details about the use of metronidazole in bacterial infections.

**Mechanism of Action**

Metronidazole is a prodrug requiring reductive activation of the nitro group by susceptible organisms. Unlike their aerobic counterparts, anaerobic and microaerophilic pathogens (e.g., the amitochondriate protozoa *T. vaginalis*, *E. histolytica*, and *G. lamblia* and various anaerobic bacteria) contain electron transport components that have a sufficiently negative redox potential to donate electrons to metronidazole. The single-electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA. Metronidazole is catalytically recycled; loss of the active metabolite's electron regenerates the parent compound. Increasing levels of O2 inhibit metronidazole-induced cytotoxicity because O2 competes with metronidazole for electrons. Thus, O2 can both decrease reductive activation of metronidazole and increase recycling of the activated drug. Anaerobic or microaerophilic organisms susceptible to metronidazole derive energy from the oxidative fermentation of ketocids such as pyruvate. Pyruvate decarboxylation, catalyzed by PFOR, produces electrons that reduce ferredoxin, which in turn catalytically donates its electrons to biological electron acceptors or to metronidazole (Lamp et al., 1999).

**Resistance**

Clinical resistance to metronidazole is well documented for *T. vaginalis*, *G. lamblia*, and a variety of anaerobic and microaerophilic bacteria.
Resistance correlates with impaired oxygen-scavenging capabilities, leading to higher local O2 concentrations, decreased activation of metronidazole, and futile recycling of the activated drug. Other resistant strains have lowered levels of PFOR and ferredoxin, perhaps explaining why they may still respond to higher doses of metronidazole (Townson et al., 1994).

**ADME**

Preparations of metronidazole are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake and distributed to a volume approximating total body water; less than 20% of the drug is bound to plasma proteins. A linear relationship between dose and plasma concentration pertains for doses of 200–2000 mg. Repeated doses every 6–8 h result in some drug accumulation. The $t_{1/2}$ of metronidazole in plasma is about 8 h. With the exception of the placenta, metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, breast milk, and CSF. After an oral dose, more than 75% of labeled metronidazole is eliminated in the urine, largely as metabolites formed by the liver from oxidation of the drug’s side chains, a hydroxyl derivative and an acid; about 10% is recovered as unchanged drug.

Two principal metabolites result. The hydroxy metabolite has a longer $t_{1/2}$ (~12 h) and has about 50% of the antichromial activity of metronidazole. Formation of glucuronides also is observed. Small quantities of reduced metabolites are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of metronidazole is inhibited by phenobarbital, prednisone, rifampin, and possibly ethanol and is inhibited by cimetidine (Lamp et al., 1999; Martinez and Caunes, 2001).

**Therapeutic Uses**

**Trichomoniasis.** Metronidazole cures genital infections with *T. vaginalis* in more than 90% of cases. The preferred treatment regimen is 2 g metronidazole as a single oral dose for both males and females. T. vaginalis, which has a longer $t_{1/2}$ than metronidazole, is also used at a 2-g single dose and appears to provide equivalent or better responses (Drugs for Parasitic Infections, 2013). When repeated courses or higher doses of the drug are required, it is recommended that intervals of 4–6 weeks elapse between courses. Leukocyte counts should occur before, during, and after each course. Treatment failures owing to the presence of metronidazole-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a 500- to 1000-mg vaginal suppository may be beneficial in refractory cases (Munzy and Schwabek, 2013).

**Amebiasis.** Metronidazole is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscess. The recommended dose is 500–750 mg metronidazole taken orally three times daily for 7–10 days (McCarthy et al., 2014) or, for children, 35–50 mg/kg/d given in three divided doses for 7–10 days (Drugs for Parasitic Infections, 2013). Amebic liver abscess has been treated successfully by short courses of metronidazole or tinidazole. *Entamoeba histolytica* persists in most patients who recover from acute amebiasis after metronidazole therapy; so it is recommended that all such individuals also be treated with a luminal amebicide.

**Giardiasis.** Tinidazole is approved for the treatment of giardiasis as a single 2-g dose and is appropriate first-line therapy (Hill and Nash, 2014). Although metronidazole has never been FDA-approved for treatment of giardiasis in the U.S., there are many years of experience with its use (Drugs for Parasitic Infections, 2013; Pasupuleti et al., 2014).

**Toxicities and Contraindications**

Common side effects are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Dysuria, cystitis, and a sense of pelvic pressure have been reported. Dizziness, vertigo, and, very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant drug discontinuation. Metronidazole also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete.

Urticaria, flushing, and pruritus indicate drug sensitivity and can require withdrawal of metronidazole (Lofmark et al., 2010). Metronidazole is a rare cause of Stevens-Johnson syndrome, which may be more common among individuals receiving high doses of metronidazole and concurrent therapy with the antihelminthic mebendazole (Chen et al., 2003).

**Drug Interactions**

Metronidazole has a disulfiram-like effect, and some patients experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy (Jang and Harris, 2007). Metronidazole and disulfiram or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur. Metronidazole should be used cautiously in patients with active disease of the CNS because of potential neurotoxicity. The drug also may precipitate CNS signs of lithium toxicity in patients receiving high doses of lithium.

Metronidazole can prolong the prothrombin time of patients receiving therapy with warfarin anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease. Metronidazole use during the first trimester of pregnancy generally is not advised (Drugs for Parasitic Infections, 2013; Lofmark et al., 2010).

**Miltefosine**

Miltefosine is an alkylphosphocholine analogue developed originally as an anticancer agent. Its antiprotozoal activity was discovered in the 1980s as it was being evaluated for cancer chemotherapy. In 2002, it was approved in India as the first orally active treatment available for visceral leishmaniasis. It is highly curative against visceral leishmaniasis and also is effective against the cutaneous forms of the disease (Magill, 2014). Its main drawback is its teratogenicity; consequently, it must not be used in pregnant women (Miltefosine (Impavido) for Leishmaniasis, 2014).

![Miltefosine](image)

**Antiprotozoal Effects**

Miltefosine is the first orally available therapy for leishmaniasis. It is a safe and effective treatment of visceral leishmaniasis and has shown greater than 90% efficacy against some species of cutaneous leishmaniasis, although significant strain variation has been noted in clinical trials (Sundar and Chakravarty, 2015). The mechanism of action of miltefosine is not understood. Studies suggest that the drug may alter ether-lipid metabolism, cell signaling, or glycosylophosphatidylinositol anchor biosynthesis (Dorlo et al., 2012). A transporter for miltefosine has been cloned by functional rescue of a laboratory-generated resistant strain of *L. donovani*. The transporter is a P-type ATPase that belongs to the aminophospholipid translocase subfamily. The basis for the drug resistance appears to be a point mutation in this transporter that leads to decreased drug uptake and thereby confers drug resistance (Perez-Victoria et al., 2003; Sundar and Chakravarty, 2015).

**ADME**

Miltefosine is well absorbed orally and distributed throughout the human body. Detailed pharmacokinetic data are lacking, with the exception that miltefosine has a long $t_{1/2}$ (1–4 weeks). Plasma concentrations are proportional to the dose (Miltefosine (Impavido) for Leishmaniasis, 2014; Sundar and Chakravarty, 2015).

**Therapeutic Uses**

In the U.S., the recommended dose for oral miltefosine for both visceral and cutaneous disease for adults over 45 kg is 150 mg/kg/d for 28 days, given in three divided doses, and for patients weighing 30–45 kg
is 100 mg/kg/d, given in two divided doses (Aronson et al., 2016; Miltefosine (Impavido) for Leishmaniasis, 2014). The compound cannot be given intravenously because it has hemolytic activity (Dorlo et al., 2012).

**Toxicity and Side Effects**

Vomiting and diarrhea are reported as frequent side effects, in up to 60% of patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and reversible. Because of its teratogenic potential, miltefosine is contraindicated in pregnant women. In fact, guidelines for miltefosine use in the U.S. state that adequate contraception must be used during treatment and for 5 months after therapy is complete (Miltefosine (Impavido) for Leishmaniasis, 2014).

**Nifurtimox and Benznidazole**

Nifurtimox and benznidazole are used to treat American trypanosomiasis caused by *T. cruzi*, while nifurtimox is also used in combination with eflorentinine for treatment of *T. brucei* (see previous discussion). Nifurtimox, a nitrofuran analogue, and benznidazole, a nitroimidazole analogue, can be obtained in the U.S. from the CDC.

**Antiprotozoal Effects and Mechanisms of Action**

Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi* (Barrett et al., 2007; Kennedy, 2013). Nifurtimox also has activity against *T. brucei* and can be curative against both early- and late-stage disease (see previous discussion of NECT). The trypanocidal effects of nifurtimox and benznidazole derive from their activation by an NADH-dependent mitochondrial nitroreductase to nitro radical anions that effect the damage leading to the genotoxic effects of the drugs. The generated nitro radical anions form covalent attachments to macromolecules, leading to cellular damage that includes lipid peroxidation and membrane injury, enzyme inactivation, and damage to DNA. Reduced nitroreductase expression through single-allele gene knockout experiments or through drug selection leads to drug resistance (Wilkinson et al., 2011).

**ADME**

Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after about 3.5 h. Less than 0.5% of the dose is excreted in urine (Paulos et al., 1989). The terminal *t*½ is about 3 h. Nifurtimox undergoes rapid biotransformation, probably via a presystemic first-pass effect, and high concentrations of several unidentified metabolites are found. Nifurtimox crosses the blood-brain barrier in mice (Jeganathan et al., 2011). Benznidazole is absorbed rapidly and reaches peak plasma levels within 3 h; the terminal elimination half-life is about 12 h (Raalfaub and Ziegler, 1979). Recent population studies have suggested that, in adults, a dose of 2.5 mg/kg/12 h maintains the trough concentration above the therapeutic range of 3–6 mg/L, indicating that the current recommended dose of 2.5 mg/kg/12 h may be higher than needed (Soy et al., 2015). In children, drug levels were found to be lower than in adults, with excellent efficacy nonetheless (Altcheh et al., 2014).

**Therapeutic Uses**

Nifurtimox and benznidazole are employed in the treatment of American trypanosomiasis (Chagas disease) caused by *T. cruzi* (Bern et al., 2011; Chatelain, 2015; Malik et al., 2015; Ribeiro et al., 2012). Nifurtimox is also used in combination with eflorentinine (NECT) for treatment of African sleeping sickness (see eflornithine section for discussion). Because of toxicity concerns, benznidazole is the preferred treatment of Chagas disease. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas disease, with parasitological cures obtained in more than 80% of these cases, although the clinical response of the acute illness to drug therapy varies with geographic region (Messenger et al., 2015). In the chronic form of the disease, parasitological cures are still possible, although the drug is less effective than in the acute stage. In a recent study of chronic Chagas patients, 94% of patients who completed treatment with 150 mg benznidazole twice daily for 60 days remained PCR negative until completion of the study at the 10-month follow-up (Molina, et al., 2014; Molina, et al., 2014). The current recommendations are that patients less than 50 years of age with either acute- or recent chronic-phase disease, without advanced cardiomyopathy, should be treated. In patients more than 50 years of age, the benefits of treatment are complicated by lowered drug tolerability. Therapy is strongly encouraged for patients who will receive immunosuppressive therapy or who are HIV positive. Therapy with nifurtimox or benznidazole should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or from blood transfusions.

Both drugs are given orally with doses recommended as described (Drugs for Parasitic Infections, 2013). For nifurtimox, adults (>17 years) with acute infection should receive 8–10 mg/kg/d in three to four divided doses for 90 days; children 1–10 years old should receive 15–20 mg/kg/d in three to four divided doses for 90 days; for individuals 11–16 years old, the daily dose is 12.5–15 mg/kg given according to the same schedule.

For benznidazole, the recommended treatment for adults (>13 years) is 5–7 mg/kg/d in two divided doses for 60 days, with children up to 12 years receiving 10–15 mg/kg/d in two divided doses for 60 days. However, some studies have suggested that total doses exceeding 300 mg/d are less well tolerated (Salvador et al., 2014). If gastric upset and weight loss occur during treatment, dosage should be reduced. The ingestion of alcohol should be avoided. Nifurtimox is used in combination with eflorentinine in treating late-stage *T. brucei gambiense* sleeping sickness.

**Toxicity and Side Effects**

Side effects range from hypersensitivity reactions (e.g., dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis) to dose- and age-dependent complications referable to the GI tract and both the peripheral nervous system and CNS (Ribeiro et al., 2012). Nausea and vomiting are common, as are myalgia and weakness. For benznidazole, the most common adverse event (occurring in 30% of patients in the first week of treatment) is urticarial dermatitis, which can be treated with antihistamines or corticosteroids. However, treatment often has to be discontinued in patients with this reaction. Bone marrow suppression can occur early during therapy, so blood cell counts should be measured every 2–3 weeks, and treatment stopped if suppression is observed. Peripheral neuropathy and GI symptoms are especially common after prolonged treatment; the latter complication may lead to weight loss and preclude further therapy. Benznidazole should be given with food to minimize GI effects. Because of the seriousness of Chagas disease and the lack of superior drugs, there are few absolute contraindications to the use of these drugs.

**Nitazoxanide**

Nitazoxanide (*N*-nitrothiazolyl) salicylamide) is an oral synthetic broad-spectrum antiparasitic agent (see Chapter 55). Nitazoxanide is FDA-approved for the treatment of cryptosporidiosis and giardiasis in adults and immunocompetent children (Wright, 2012).

**Antimicrobial Effects**

Nitazoxanide and its active metabolite, tizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites and oocytes of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis* in vitro (Wright, 2012). Nitazoxanide also has activity against intestinal helminthes (van den Enden, 2009).

**Mechanism of Action**

Nitazoxanide interferes with the PFOR enzyme-dependent electron transfer reaction, which is essential to anaerobic metabolism in protozoan and bacterial species (Raether and Hanel, 2003).

**ADME**

Following oral administration, nitazoxanide is hydrolyzed rapidly to its active metabolite, tizoxanide, which undergoes conjugation to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum
**Pentamidine**

Pentamidine is a positively charged aromatic diamine. It is a broad-spectrum agent with activity against several species of pathogenic protozoa and some fungi. Pentamidine as the di-isethionate salt is marketed for injection or as an aerosol (De et al., 1986; Rex and Stevens, 2014).

---

**Mechanism of Action and Resistance**

Pentamidine is used for the treatment of early-stage *T. brucei gambiense* infection but is ineffective in the treatment of late-stage disease and has reduced efficacy against *T. brucei rhodesiense* (Barrett et al., 2007; Kennedy, 2013). Pentamidine is an alternative agent for the treatment of cutaneous leishmaniasis (Monge-Maillo and Lopez-Velez, 2013). Pentamidine is an alternative agent for the treatment and prophylaxis of pneumonia caused by *Pneumocystis jiroveci* (PJP), formerly known as *Pneumocystis carinii* (PCP) (Castro, 1998). See Chapter 61, on antifungal agents, for additional details.

**Diminazene** (not available in the U.S.) is a related diamidine that is used as an inexpensive alternative to pentamidine for the treatment of early African trypanosomiasis and has been used outside the U.S. for the treatment of early-stage *T. brucei gambiense* in periods of pentamidine shortage (Munday et al., 2015).

**ADME**

Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent t₁/₂ of several minutes to a few hours; maximum plasma concentrations after intramuscular injection occur at 1 h. The t₁/₂ of elimination is long (weeks to months); the drug is 70% bound to plasma proteins (Bronner et al., 1995). This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining its ineffectiveness against late-stage trypanosomiasis.

---

**Therapeutic Uses**

African Trypanosomiasis. Pentamidine isethionate is used for the treatment of early-stage *T. brucei gambiense* and is given by intramuscular or intravenous injection in doses of 4 mg/kg daily for 7 days.

Leishmaniasis. Pentamidine can be used in doses of 2–3 mg/kg IV or IM daily or every second day for 4–7 doses to treat cutaneous leishmaniasis (Drugs for Parasitic Infections, 2013). This compound provides an alternative to antimonials, lipid formulations of amphotericin B, or miltefosine, but it is overall the least well tolerated (Monge-Maillo and Lopez-Velez, 2013).

**Toxicity and Side Effects.** Approximately 50% of individuals receiving the drug at recommended doses show some adverse effect (Barrett et al., 2007). Intravenous administration of pentamidine may be associated with hypotension, tachycardia, and headache. These effects can be ameliorated by slowing the infusion rate. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. Pentamidine is nephrotoxic (~25% of treated patients show signs of renal dysfunction), and if the serum creatinine concentration rises, it may be necessary to withdraw the drug temporarily or change to an alternative agent (Rex and Stevens, 2014). Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic
enzymes (Salamone and Cunha, 1988). Intramuscular administration of pentamidine is associated with the development of sterile abscesses at the injection site, which can become infected secondarily; most authorities recommend intravenous administration (Cheung et al., 1993).

**Sodium Stibogluconate**

Antimonials were introduced in 1945 and have been used for therapy of leishmaniasis and other protozoal infections. The first trivalent antimonial compound used to treat cutaneous leishmaniasis and kala azar was antimony potassium tartrate (tartar emetic), which was both toxic and difficult to administer. Tartar emetic and other trivalent arsenicals eventually were replaced by pentavalent antimonial derivatives of phenylstibonic acid. An early member of this family of compounds was sodium stibogluconate (sodium antimony gluconate), a pentavalent antimonial compound that has been the mainstay of the treatment of leishmaniasis. Increasing resistance to antimonials has reduced their efficacy (WHO, 2015c). In the U.S., sodium stibogluconate can be obtained from the CDC (Aronson et al., 2016).

**Mechanism of Action**

The pentavalent antimonials act as prodrugs that are reduced to the more toxic SbV species that kill amastigotes within the phagolysosomes of macrophages. Following reduction, the drugs seem to interfere with the trypanothione reductase. SbV induces a rapid efflux of trypanothione and glutathione from the cells and also inhibits trypanothione reductase, thereby causing a significant loss of thiol potential reduction in the cells (Frezard et al., 2009).

**ADME**

The drug is given intravenously or intramuscularly; it is not active orally. The agent is absorbed rapidly and distributed in an apparent volume of about 0.22 L/kg. Elimination occurs in two phases, the first with a t1/2 of about 2 h, the second with a much longer half-time (33–76 h). The prolonged terminal elimination phase may reflect conversion of the SbV to the more toxic SbVI that is concentrated in and only slowly released from tissues. The drug is eliminated in the urine (Frezard et al., 2009).

**Therapeutic Uses**

Sodium stibogluconate is given parenterally. The standard course is 20 mg/kg/d for 20 days for cutaneous disease and for 28 days for visceral leishmaniasis (Drugs for Parasitic Infections, 2013; McCarthy et al., 2014). Increased resistance has greatly complicated the effectiveness of antimonials, and sodium stibogluconate is now obsolete in India. Previously, liposomal amphotericin B was the recommended alternative, but now the orally effective compound miltefosine is likely to see much wider use (Sundar and Chakravarty, 2015). Intramuscular treatment has also been advocated as a safer, alternative method for treating cutaneous disease (Monge-Maillo and Lopez-Velez, 2013). Patients who respond show clinical improvement within 1–2 weeks of initiating therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals (Sundar and Chakravarty, 2015). Patients infected with HIV often relapse after therapy (Magill, 2014).

**Toxicity and Side Effects**

In general, regimens of sodium stibogluconate are tolerated; toxic reactions usually are reversible, and most subside despite continued therapy; Adverse effects include chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression, manifested by decreased red cell, white cell, and platelet counts; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial toxicity, as are shock and sudden death (Frezard et al., 2009).

**Suramin**

Research into the trypanocidal activity of the dyes trypan red, trypan blue, and afridal violet led to the introduction of suramin into therapy in 1920. Today, the drug is used primarily for treatment of African trypanosomiasis; it has no clinical utility against American trypanosomiasis.

**Suramin sodium** is a water-soluble trypanocide; solutions deteriorate quickly in air, and only freshly prepared solutions should be used. In the U.S., suramin is available only from the CDC.

**Antiparasitic Effects**

Suramin is a relatively slow-acting trypanocide (>6 h in vitro) with high clinical activity against both *T. brucei gambiense* and *T. brucei rhodesiense*. Its mechanism of action is unknown, although a recent study has suggested a role for lysosomal function in suramin action (Alsford et al., 2012). This same study also found that the invariant surface glycoprotein (ISG75) family mediates suramin uptake into the parasite. Selective toxicity is likely to result from selective uptake by the parasite. Suramin inhibits many trypanosomal and mammalian enzymes and receptors. No consensus for the mechanism of action has emerged, and the lack of any significant field resistance points to multiple potential targets.

**ADME**

Because it is not absorbed after oral intake, suramin is given intravenously to avoid local inflammation and necrosis associated with subcutaneous or intramuscular injections (Kaur et al., 2002). After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The drug is 99.7% serum protein bound and has a terminal elimination t1/2 of 41–78 days. Suramin is not appreciably metabolized; renal clearance accounts for elimination of about 80% of the compound from the body. Very little suramin penetrates the CSF, consistent with its polar character and lack of efficacy once the CNS has been invaded by trypanosomes.

**Therapeutic Uses**

Suramin is the first-line therapy for early-stage *T. brucei rhodesiense* infection (Barrett et al., 2007; Kennedy, 2013; McGearry et al., 2008). It also is active against *T. brucei gambiense* but is only used as a second-line treatment if pentamidine fails or is otherwise contraindicated. Because only small amounts of the drug enter the brain, suramin is used only for the treatment of early-stage African trypanosomiasis (before CNS involvement). Treatment of active African trypanosomiasis should not be started until 24 h after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (i.e., pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia, hypotension, and possibly permanent blindness). Suramin is given by slow intravenous injection as a 10% aqueous solution. The normal single dose for adults with *T. brucei rhodesiense* infection is 1 g. It is advisable to employ a test dose of 100 mg initially to detect sensitivity, after which the normal dose is given intravenously (e.g., on days 1, 3, 5, 14, and 21). The pediatric test dose is 2 mg/kg followed by a dose of 20 mg/kg, given according to the same schedule as adults. Patients in poor condition should be treated with lower doses during the first week. Patients who relapse after suramin therapy should be treated with melarsoprol.

**Toxicity and Side Effects**

The most serious immediate reaction, consisting of nausea, vomiting, shock, and loss of consciousness, is rare (~1 in 2000 patients) (Kaur et al., 2002). Malaise, nausea, and fatigue are also common immediate reactions. The most common problem encountered after several doses of suramin is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. Other, less-prevalent reactions include vomiting, diarrhea, stomatitis, chills, abdominal pain, and edema. Patients receiving suramin should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency.

Chapter 55

ANTHELMINTIC DRUGS
- Benzimidazoles
- Diethylcarbamazine
- Doxycycline
- Ivermectin
- Praziquantel
- Metrifonate
- Oxamniquine
- Niclosamide
- Oxantel and Pyrantel Pamoate
- Tribendimidine
- Moxidectin
- Levamisole
- Nitazoxanide
- Albendazole
- Mebendazole
- Triclabendazole
- Thiabendazole

Anthelmintic Drugs
Although a large number of anthelmintic drugs have been approved for human use, only a small number are widely used for treatment of helminth infections that occur worldwide (Figure 55–1). These include two drugs in the benzimidazole (BZ) class, albendazole and mebendazole, which are widely used for treatment of intestinal nematode and cestode infections; the macrocyclic lactone ivermectin, used to treat a variety of nematode and ectoparasite infections; and praziquantel, which is used to treat trematode and some cestode parasites. Because of their role in programs of mass drug administration (MDA), these drugs are amongst the most commonly used agents worldwide. WHO estimated that through MDA approximately 853 million people received one or more anthelmintic drugs in 2014 (WHO, 2016). In many resource-poor developing countries, several different anthelmintic drugs can be provided together through integrated programs of MDA to simultaneously target intestinal and filarial nematodes and trematodes (Webster et al., 2014). Key drugs, their indications, and important pharmacologic properties are listed in the Drug Facts table.

Benzimidazoles
Although a large number of drugs in this class have been synthesized and several have undergone clinical development for treatment of parasitic infections of humans, only two are currently in wide use, namely, albendazole and mebendazole, with triclabendazole reserved for treatment of liver fluke infection caused by Fasciola hepatica. Thiabendazole was formerly recommended for treatment of strongyloidiasis, but ivermectin is more effective and better tolerated.

Chemistry
Albendazole, mebendazole, and triclabendazole are all poorly water soluble and only slightly soluble in methanol. The chemical structures of these drugs are shown in Figure 55–2.

Mechanism of Action
The primary mechanism of action of BZs is thought to be inhibition of microtubule polymerization by binding to β-tubulin (Prichard, 1994). The selective toxicity of these agents against helminths results from their higher affinity for parasite β-tubulin than for the same target in higher eukaryotes. A range of other biochemical changes occurs in nematodes following BZ exposure, including inhibition of mitochondrial fumarate reductase, reduced glucose transport, and uncoupling of oxidative phosphorylation.

ADME
Mebendazole. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass metabolism at the intestinal wall and in the liver. Coadministration of cimetidine increases plasma levels of mebendazole, possibly due to inhibition of first-pass, CYP-mediated metabolism (Dayan, 2003). The small proportion of mebendazole that is absorbed is about 95% bound to plasma proteins and is extensively metabolized. Mebendazole, rather than its metabolites, appears to be the active drug form (Gottschall et al., 1990). Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine.

Albendazole. Albendazole is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods and possibly by bile salts. Administration following food, especially a fatty meal, enhances absorption by up to 5-fold in humans (Dayan, 2003). Cimetidine decreases albendazole bioavailability. The activity of albendazole against tissue-dwelling helminths is attributable to its active metabolite, albendazole sulf oxide. The better bioavailability of the parent drug and the activity of albendazole sulf oxide explain why albendazole is more active than mebendazole against tissue-dwelling helminths. The level of albendazole sulf oxide is enhanced 3.2-fold by grapefruit juice. However, grapefruit juice shortens its t½ by 46%. It has been suggested that albendazole is metabolized by CYP3A4 enzymes in the intestinal mucosa, a process that can be inhibited by grapefruit juice (Nagy et al., 2002). After a 400-mg oral dose, albendazole cannot be detected in plasma because the drug is rapidly metabolized in the liver and possibly in the intestine, to albendazole sulf oxide, which has potent anthelmintic activity (Redondo et al., 1999).

Both the (+) and (–) enantiomers of albendazole sulf oxide are formed; the (+) enantiomer reaches much higher peak plasma concentrations in humans and is cleared much more slowly than the (–) form (Marques et al., 1999). Albendazole sulf oxide is about 70% bound to plasma proteins and has a highly variable plasma t½ of 4–15 h (Marques et al., 1999). It is well distributed into various tissues, including hydatid cysts, where it reaches a concentration of about 20% that in plasma (Morris et al., 1987). Oxidation of the sulf oxide derivatives to the nonchiral sulfone metabolite of albendazole, which is pharmacologically inactive, is probably rate limiting in determining the clearance and therefore the plasma t½ of the bioactive (+) sulf oxide metabolite. In animal models, BZs can induce their own metabolism (Gleizes et al., 1991). Albendazole metabolites are excreted mainly in the urine.

Triclabendazole. Administration of triclabendazole after food enhances its absorption, which might be due to the stimulation of gastric acid secretion, food-induced increase in drug solubility, or altered GI motility and transit time. After oral administration, triclabendazole is rapidly oxidized into two major metabolites, triclabendazole sulf oxide and triclabendazole sulfone, and only low concentrations of the parent drug can be detected...
in plasma. Triclabendazole sulfoxide is the metabolite active against E. hepatica (Keiser et al., 2005).

**Therapeutic Uses**

**Mebendazole.** Mebendazole is an effective drug for treatment of some GI nematode infections. It is only administered orally, with the same dosage schedule applying to adults and to children more than 2 years of age. For treatment of enterobiasis, a single 100-mg tablet is taken; if the patient is not cured, a second dose should be given after 3 weeks. For control of GI nematode infections. It is only administered orally, with the same dosage schedule applying to adults and to children more than 2 years of age.

**Albendazole.** Albendazole is a safe and highly effective therapy for infections with GI nematodes, including Ascaris lumbricoides, Trichuris trichiura, and hookworms. For programmatic control of soil-transmitted helminth infections (STH) infections (enterobiasis, ascariasis, trichuriasis, and hookworm), albendazole is administered as a single oral 400-mg dose to adults and children more than 2 years of age. Cure rates for light-to-moderate Ascaris infections typically are more than 97%, although heavy infections may require therapy for 2–3 days. A 400-mg dose of albendazole appears to be superior to a 500-mg dose of mebendazole for curing hookworm infections and reducing egg counts (Keiser and Utzinger, 2008). A 3-day regime of albendazole outperforms single-dose treatments against hookworm and T. trichiura infections (Steinmann et al., 2011). When administered at a dose of 400 mg daily for 3 days, albendazole shows some efficacy in treatment of strongyloidiasis but is less effective than ivermectin for treatment of this infection (Marti et al., 1996).

Albendazole is the drug of choice for chemotherapy of cystic hydatid disease due to Echinococcus granulosus. Although prolonged treatment with the drug leads to only a modest cure rate, it is useful as adjunctive treatment in the perioperative period to reduce the risk of disseminated infection resulting from spillage of cyst contents at the time of surgery or with nonoperative puncture, aspiration, injection, reaspiration (PAIR) procedures (Horton, 1997; Schantz, 1999). A typical dosage regimen for adults is 400 mg given twice a day (for children, 15 mg/kg per day with a maximum of 800 mg) for 1–6 months. Although it is the only drug available with useful activity against alveolar echinococcosis caused by Echinococcus multilocularis (Venkatesan, 1998), it is parasitostatic rather than parasitocidal, and lifelong therapy with or without surgical intervention is usually required to control this infection.

Albendazole also is the preferred treatment of neurocysticercosis caused by larval forms of Taenia solium (Evans et al., 1997; Garcia and Del Brutto, 2000). The recommended dosage is 400 mg given twice a day for adults for 4–30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg per day (maximum 800 mg) in two doses for 8–30 days. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoid therapy is usually begun before initiating albendazole therapy and is continued for several days after commencement of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysterci. Glucocorticoids increase plasma levels of albendazole sulfoxide. Prior to initiating chemotherapy of neurocysticercosis, consideration should be given to close observation or the administration of presumptive anticonvulsant therapy. Possible complications include arachnoiditis, vasculitis, cerebral edema, damage to the orbit or spinal cord, and the need for surgical intervention should obstructive hydrocephalus occur. A recent randomized trial indicated that albendazole in combination with praziquantel showed superior efficacy against neurocysticercosis compared to albendazole alone, either in standard or high dose (Garcia et al., 2014).

Albendazole, 400 mg per day, also has shown efficacy for therapy of certain microsporidal intestinal infections in patients with AIDS. Infection with Capillaria philippinensis can be treated with a 10-day treatment regimen with albendazole (400 mg/d).

Albendazole has been combined with DEC, ivermectin, or DEC plus ivermectin in programs directed toward controlling LF in most parts of the world (Molyneux and Zagaria, 2002; Ottesen et al., 1999; Thomsen et al., 2016). The strategy is annual dosing with combination therapy for
4–6 years to maintain the microfilaraemia at such low levels that transmission cannot occur. The period of therapy is estimated to correspond to the duration of fecundity of adult worms. To avoid serious reactions to dying microfilariae, the albendazole/ivermectin combination is recommended in locations where filariasis coexists with either onchocerciasis or loiasis.

**Triclabendazole.** Triclabendazole is used for the treatment of fascioliasis and represents an alternative to praziquantel for treatment of paragonimiasis. Triclabendazole is administered at 10 mg/kg with a repeated dose administered when patients have high infection intensities (Keiser et al., 2005).

**Adverse Effects; Drug Interactions**

Apart from thiabendazole, the BZs have excellent safety profiles. Overall, the incidence of side effects, primarily mild GI symptoms, occur in only 1% of treated children. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness. Mebendazole does not cause significant systemic toxicity in routine clinical use, which may be due to its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infection and expulsion of GI worms.

Albendazole produces few side effects when used for short-term therapy of GI helminth infections, even in patients with heavy worm burdens. In long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is liver dysfunction, generally manifested by an increase in serum transaminase levels; rarely, jaundice may be noted, but liver enzymes return to normal after therapy is completed. Liver function tests should be monitored during prolonged albendazole therapy; the drug is not recommended for patients with cirrhosis. The safety of albendazole in children less than 2 years of age has not been established. Long-term albendazole therapy can occasionally cause bone marrow toxicity, so blood counts should be monitored in this setting as well.

The BZs as a group display few clinically significant interactions with other drugs. Albendazole may induce its own metabolism; plasma levels of its sulfoxide metabolites can be increased by coadministration of glucocorticoids and possibly praziquantel. Due to theoretical considerations, caution is advised when using high doses of albendazole together with drugs that inhibit hepatic CYPs, such as ritonavir. Coadministration of cimetidine can increase the bioavailability of mebendazole.

**Pediatric and Geriatric Indications and Problems**

Although neither albendazole nor mebendazole is recommended for use in pregnancy, a review of the risk of congenital abnormalities from BZs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects. Hookworm infections occur in many pregnant women in developing countries, including up to one-third of pregnant women in sub-Saharan Africa. Because of the increased morbidity conferred by iron deficiency anemia in pregnancy, monthly BZ treatment has been recommended by the WHO during the second and third trimesters of pregnancy on the basis that improved iron status due to eradication of hookworm infection has a demonstrable benefit for both mother and child. Nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy. There is no evidence that maternal BZ therapy presents a risk to breastfed infants.

The BZs have not been extensively studied in children less than 2 years of age. The WHO concluded that BZs may be used in children more than 1 year old if the risks from adverse consequences caused by STHs are outweighed by the benefits of therapy. The WHO recommends that treatment with BZs be delayed until the age of 1 year if the risks from adverse consequences caused by STHs are minimal. The WHO recommended curative doses of BZs for use in children are 1 mg/kg, repeated daily for 3 days, in children between the ages of 12 and 24 months.

**Diethylcarbamazine**

**Chemistry**

*Diethylcarbamazine* (N,N-diethyl-4-methylpiperazine-1-carboxamide) is formulated as the water-soluble citrate salt containing 51% by weight of the active base. The drug is soluble in water. Because the compound is tasteless, odorless, and stable to heat, it also can be taken in the form of fortified table salt containing 0.2%–0.4% by weight of the base. The drug is available outside the U.S.; in the U.S., it is supplied by the CDC.

**Mechanism of Action**

The mechanisms of action of DEC against filarial species are unknown. Microfilarial forms of susceptible filarial species are most affected by DEC. These developmental forms of *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa* rapidly disappear from human blood after consumption of the drug. Microfilariae of *Onchocerca volvulus* rapidly disappear from skin after DEC administration, but the drug does not kill microfilariae in nodules that contain the adult (female) worms. The drug has some activity against the adult life-cycle stages of *W. bancrofti*, *B. malayi*, and *L. loa* but negligible activity against adult *O. volvulus*.

**ADME**

Diethylcarbamazine is absorbed rapidly from the GI tract. Peak plasma levels occur within 1–2 h; the plasma t½ varies from 2 to 10 h, depending on the urinary pH. Alkalinizing the urine can elevate plasma levels, prolong the plasma t½, and increase both the therapeutic effect and the toxicity of DEC (Awadzi et al., 1986). Dosage reduction may be required for people with renal dysfunction. Metabolism is rapid and extensive; a major metabolite, DEC-N-oxide, is active.

**Therapeutic Uses**

Recommended regimens differ according to whether the drug is used for population-based chemotherapy, treatment of confirmed filarial infection, or prophylaxis against infection.

- *Wuchereria bancrofti*, *B. malayi*, and *B. timori*. The standard regimen for the treatment of LF traditionally has been a 12-day, 6 mg/kg/d course of DEC. In the U.S., it is common practice to administer small test doses of 50–100 mg (1–2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg reportedly has comparable macrofilaricidal and microfilaricidal efficacy to the standard regimen (Addiss and Dreyer, 2000). Single-dose therapy may be repeated every 6–12 months, as necessary. Although DEC does not reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent progression of lymphatic damage. For mass treatment to interrupt transmission, effective strategies have included the introduction of DEC into table salt (0.2%–0.4% by weight of the base) (Gelband, 1994). DEC, given annually as a single oral dose of 6 mg/kg, is most effective in reducing microfilaraemia when coadministered with either albendazole (400 mg) or ivermectin (0.2–0.4 mg/kg). Therapy is usually well tolerated.

- *Onchocerca volvulus* and *L. loa*. DEC is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions (Molyneux et al., 2003), and ivermectin is the preferred drug for this infection. DEC is the drug of choice for therapy of loiasis with some caveats (as discussed in the following material). Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2–3 days, escalating to maximally tolerated daily doses of 9 mg/kg in three doses for 2–3 weeks. In patients with high-grade microfilaraemia, low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae. Albendazole may be useful in patients who either fail therapy with DEC or who cannot tolerate the drug. DEC is clinically effective against microfilariae and adult worms of *D. streptocerca*. DEC is no longer recommended as a first-line drug for the treatment of toxocariasis.

**Adverse Effects**

Below a daily dose of 8–10 mg/kg, direct toxic reactions to DEC are rarely severe and usually disappear within a few days despite continuation of...
therapy. These reactions include anorexia, nausea, headache, and, at high doses, vomiting. Major adverse effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae. Delayed reactions to dying adult worms may result in lymphangitis, swelling, and lymphoid abscesses in bancroftian and brugian filariasis and small skin wheals in loiasis. The drug occasionally causes severe side effects in heavy *L. loa* infections, including retinal hemorrhage and life-threatening encephalopathy. In patients with onchocerciasis, the *Mazzotti* reaction typically occurs within a few hours after the first dose. No significant drug interactions have been reported with DEC.

**Precautions and Contraindications**

Population-based therapy with DEC should be avoided where onchocerciasis or loiasis may be endemic in sub-Saharan Africa, although the drug can be used to protect foreign travelers from these infections. Pre-treatment with glucocorticoids and antihistamines is undertaken to minimize indirect reactions to DEC that result from release of antigen by dying microfilariae. Dosage reduction may be appropriate for patients with impaired renal function or persistent alkaline urine. DEC should be safe to use during pregnancy.

**Mechanism of Action**

Ivermectin immobilizes affected organisms by inducing tonic paralysis of the musculature. Avermectins induce paralysis by activating a family of ligand-gated Cl⁻ channels, particularly glutamate-gated Cl⁻ channels found only in invertebrates. Ivermectin probably binds to glutamate-activated Cl⁻ channels found in nematode nerve or muscle cells and causes hyperpolarization by increasing intracellular chloride concentration, resulting in paralysis. Glutamate-gated Cl⁻ channels probably are one of several sites of ivermectin action amongst invertebrates (Zufall et al., 1989). Avermectins also bind with high affinity to GABA-gated and other ligand-gated Cl⁻ channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined. Lack of high-affinity avermectin receptors in ceptodes and trematodes may explain why these helminths are not sensitive to ivermectin (Shoop et al., 1993). Avermectins also interact with GABA receptors in mammalian brain, but their affinity for invertebrate receptors is about 100-fold higher (Schaeffer and Haines, 1989).

**Therapeutic Uses**

**Onchocerciasis.** Ivermectin, administered as a single oral dose (150–200 μg/kg) given every 6–12 months, is the drug of choice for onchocerciasis in adults and children 5 years or older (Goa et al., 1991). Marked reduction of microfilariae in the skin results in major relief of the intense pruritus that is a feature of onchocerciasis. Clearance of microfilariae from skin and ocular tissues occurs within a few days and lasts for 6–12 months; the dose then should be repeated. However, the drug is not curative because ivermectin has little effect on adult *O. volvulus*. Annual doses of the drug are quite safe and substantially reduce transmission of this infection.

**Lymphatic Filariasis.** Ivermectin is as effective as DEC for controlling LF, and unlike DEC, it can be used in regions where onchocerciasis, loiasis, or both are endemic (Ottesen and Ramachandran, 1995). A single annual dose of ivermectin (200 μg/kg) and a single annual dose of albendazole (400 mg) are even more effective in controlling LF than either drug alone (Ottesen et al., 1999). The duration of treatment is at least 5 years, based on the estimated fecundity of the adult worms.

**Strongyloidiasis.** Ivermectin, administered as a single dose of 150 to 200 μg/kg, is the drug of choice for human strongyloidiasis (Marti et al., 1996). It is generally recommended that a second dose be administered a week following the first dose. This regimen is more efficacious than a 3-day course of albendazole.

**Infections With Other Intestinal Nematodes.** Ivermectin is more effective in ascariasis and enterobiasis than in trichuriasis or hookworm infection. In the last two infections, although it is not curative, it significantly reduces the intensity of infection.

**Other Indications.** Taken as a single 200-μg/kg oral dose, ivermectin is a first-line drug for treatment of cutaneous larva migrans caused by dog or cat hookworms and is an option for treatment of scabies and head lice. In uncomplicated scabies, two doses should be administered, 1–2 weeks apart. In severe (crusted) scabies, ivermectin should be used in repeated doses, with one recommended regimen entailing seven doses of 200 μg/kg given with food on days 1, 2, 8, 9, 15, 22, and 29. It also is effective in community-driven control programs (Roman et al., 2015). The drug formulated as a topical 0.2% lotion is active against human head lice (Pariser et al., 2012).

**Adverse Effects; Drug Interactions**

Ivermectin is well tolerated by uninfected humans. In filarial infection, ivermectin therapy frequently causes a *Mazzotti*-like reaction to dying microfilariae. The intensity and nature of these reactions relate to the
Praziquantel is a pyrazinoisoquinoline derivative, a racemate, consisting of the biologically active enantiomer, R-praziquantel and the inactive isomer S-praziquantel. The white crystalline powder is slightly soluble in water and freely soluble in alcohol and in methylene chloride.

**Mechanism of Action**

Praziquantel has two major effects on adult schistosomes. At the lowest effective concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls and migrate from the mesenteric veins to the liver. At slightly higher concentrations, praziquantel causes tegumental damage and exposes a number of tegumental antigens (Redman et al., 1996). The clinical efficacy of this drug correlates better with tegumental action (Xiao et al., 1985). The drug is ineffective against juvenile schistosomes and therefore is relatively ineffective in early infection. An intact immune response is believed to be required for the clinical efficacy of the drug.

The primary site of action of praziquantel is uncertain (Aragon et al., 2008). Praziquantel inhibits adenosine flux (Angelucci et al., 2007), but definitive evidence that this action contributes to the anthelmintic effect is lacking.

**Precautions and Contraindications**

Because of its effects on GABA receptors in the CNS, ivrvermectin is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). In programs of MDA where loiasis is coendemic with either onchocerciasis or LF, ivermectin should be used with caution and in consultation with local or international experts.

**Praziquantel Chemistry**

Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. A single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4–6 h apart, generally produce cure rates of 70%–95% and consistently high reductions (>85%) in egg counts (Utzinger and Keiser, 2004). Three doses of 25 mg/kg taken 4–8 h apart result in high rates of cure for infections with the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini* or the intestinal flukes *Fasciolopsis buski*, *Heteroparyx heterophryes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke *Paragonimiasis westermani*. The liver fluke *F. hepatica* is resistant to praziquantel and should be treated with triclabendazole (Keiser et al., 2005). Low doses of praziquantel can be used to treat intestinal infections with adult cestodes (a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Dipylidibothrium latum, Taenia solitaria*, or *T. solium*). Re-treatment after 7–10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be coadministered in this condition (Evans et al., 1997).

**Adverse Effects; Drug Interactions**

Abdominal discomfort and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and may be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2–3 days, and respond to analgesics and anticonvulsants. Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Driving and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the exposure times of praziquantel; these direct effects are transient and dose related. Indirect effects such as tachycardia, hypotension, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may result in high rates of cure for infections with the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini* or the intestinal flukes *Fasciolopsis buski*, *Heteroparyx heterophryes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke *Paragonimiasis westermani*. The liver fluke *F. hepatica* is resistant to praziquantel and should be treated with triclabendazole (Keiser et al., 2005). Low doses of praziquantel can be used to treat intestinal infections with adult cestodes (a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Dipylidibothrium latum, Taenia solitaria*, or *T. solium*). Re-treatment after 7–10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be coadministered in this condition (Evans et al., 1997).

**Therapeutic Uses**

Re-treatment after 7–10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be coadministered in this condition (Evans et al., 1997).

**Adverse Effects; Drug Interactions**

Abdominal discomfort and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and may be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2–3 days, and respond to analgesics and anticonvulsants. Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Driving and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the exposure times of praziquantel; these direct effects are transient and dose related. Indirect effects such as tachycardia, hypotension, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may result in high rates of cure for infections with the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini* or the intestinal flukes *Fasciolopsis buski*, *Heteroparyx heterophryes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke *Paragonimiasis westermani*. The liver fluke *F. hepatica* is resistant to praziquantel and should be treated with triclabendazole (Keiser et al., 2005). Low doses of praziquantel can be used to treat intestinal infections with adult cestodes (a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Dipylidibothrium latum, Taenia solitaria*, or *T. solium*). Re-treatment after 7–10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be coadministered in this condition (Evans et al., 1997).

**Mefronatone**

Mefronatone (trichlorfon) is an organophosphorus compound used first as an insecticide and later as an anthelmintic, especially for treatment of *Schistosoma haematobium*. It remains a second-line drug for this indication. Mefronatone is a prodrug; at physiological pH, it is converted nonenzymatically to dichlorvos (DDVP), a potent cholinesterase inhibitor.
Oxamnique
Oxamnique is a second-line drug after praziquantel for the treatment of Schistosoma mansoni infection. Schistosoma haematobium and Schistosoma japonicum are refractory to this drug.

Niclosamide
Niclosamide, a halogenated salicylanilide derivative, was introduced for human use as a taenicide. Niclosamide is no longer approved for use in the U.S. It has some use in intestinal T. solium infection where neurocysticercosis is present or cannot be excluded.

Oxantel and Pyrantel Pamoate

**Chemistry**
The tetrahydropyrimidine analogues include pyrantel pamoate and the m-oxyphenol analogue of pyrantel, oxantel pamoate. Both drugs are practically insoluble in water and alcohol.

**Mechanism of Action**
Pyrantel and its analogues are depolarizing neuromuscular blocking agents. They open nonselective cation channels and induce persistent activation of nicotinic acetylcholine receptors and spastic paralysis of the worm (Robertson et al., 1994). Pyrantel pamoate is active at the L type, while oxantel pamoate is active on the N subtype of nicotinic acetylcholine receptors (Williamson et al., 2009).

Pyrantel also inhibits cholinesterases. It causes a slowly developing contracture of isolated preparations of Ascaris at 1% of the concentration of acetylcholine required to produce the same effect. Pyrantel exposure leads to depolarization and increased spike-discharge frequency, accompanied by increases in tension, in isolated helminth muscle preparations.

**ADME**
Pyrantel pamoate and oxantel pamoate are poorly absorbed from the GI tract, a property that confines their action to intraluminal GI nematodes. Less than 15% of pyrantel pamoate is excreted in the feces.

**Therapeutic Uses**
Pyrantel pamoate is an alternative to mebendazole or albendazole for treatment of ascariasis and enterobiasis. High cure rates are achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. Pyrantel also is effective against hookworm infections caused by Ancylostoma duodenale and Necator americanus, although repeated doses are needed to cure heavy infections by N. americanus. The drug should be used in combination with oxantel pamoate for mixed infections with *T. trichiura*. Indeed, oxantel pamoate was shown to have a higher efficacy than the BZs mebendazole and albendazole against infections with *T. trichiura* (Speich et al., 2016). Oxantel pamoate combined with albendazole is a highly effective combination in the treatment of ascariasis, trichuriasis, and hookworm infections. For pinworm infections, repeat the treatment after an interval of 2 weeks.

**Adverse Effects; Drug Interactions**
Transient and mild GI symptoms occasionally occur, as do headache, dizziness, rash, and fever. Pyrantel pamoate has not been studied in pregnant women.

**Tribendimidine**
Tribendimidine is a drug that has been marketed in China for over a decade. Given the efforts to introduce the drug to Western markets, it is included in this chapter.

**Chemistry**
Tribendimidine (a symmetrical diamidine derivative) is a yellow crystalline powder that does not dissolve in water and only marginally in anhydrous ethanol, methanol, and acetone. It dissolves in chloroform (Xiao et al., 2005).

**Mechanism of Action**
Tribendimidine is an agonist of muscle nicotinic acetylcholine receptors of parasitic nematodes. Tribendimidine is more selective for the B subtype than the L subtype of nicotinic acetylcholine receptors; hence, it can activate a different population of nematode parasite nicotinic acetylcholine receptors. This might explain why tribendimidine exhibits activity on a levamisole-resistant isolate of *Oesophagostomum dentatum* and why the spectrum of action of tribendimidine is broader (covering also the trematodes *C. sinensis* and *O. viverrini* and cestodes) to that of other cholinergic anthelmintics like levamisole (Robertson et al., 2015).

**ADME**
Tribendimidine pharmacokinetics has been studied in Chinese healthy volunteers (Yuan et al., 2010) and in patients infected with *O. viverrini* (Duthaler et al., 2015). Tribendimidine cannot be detected in plasma. It is rapidly and completely broken down to dADT, which is the active metabolite and TPAL. Furthermore, dADT undergoes metabolism to acetylated dADT, and TPAL is transformed into TPAC. The *t*_½ of dADT was 4.7 h in healthy volunteers following 400 mg of tribendimidine. Tribendimidine is mainly excreted through the urine (Yuan et al., 2010).

**Therapeutic Uses**
Tribendimidine is given to children below 15 years of age and adults at doses of 200 mg and 400 mg, respectively. With regard to STH infections, tribendimidine has a similar activity profile as albendazole: Tribendimidine shows high cure and egg reduction rates against *A. lumbricoides*, moderate-to-good efficacy against hookworm, and a low cure rate but moderate egg reduction rates against *T. trichiura*. Against pinworm infections, cure rates with tribendimidine were 74.1% (single dose) and 97.1% (two doses) (Xiao et al., 2013). Tribendimidine has high activity against *C. sinensis* and *O. viverrini*: Single dosages of tribendimidine (200 and 400 mg) showed similar efficacy than multiple treatments with praziquantel (Qian et al., 2013; Soukhathammavong et al., 2011). The efficacy of tribendimidine against strongyloides and cestode infections remains to be studied.

**Adverse Effects; Drug Interactions**
Tribendimidine shows a good safety profile. Adverse effects (e.g., dizziness, vertigo, headache, nausea, vomiting, and fatigue) are mainly mild and self-limiting. Drug interactions have not yet been studied thoroughly.
**Moxidectin**

Moxidectin, a macrocyclic lactone related to ivermectin, is currently under development for the treatment of onchocerciasis and perhaps other helminth infections.

**Chemistry**

Moxidectin, a white or pale yellow powder, is slightly soluble in water but readily soluble in organic solvents.

**Mechanism of Action**

The mechanism of action of the avermectins has been described previously. A difference has been demonstrated between ivermectin and moxidectin for interacting with GABA-gated Cl⁻ channels. In contrast to ivermectin, moxidectin is a poor substrate for P-glycoproteins, hence suggesting a different mechanism or susceptibility to resistance (Cobb and Boeckh, 2009).

**ADME**

Pharmacokinetic parameters were dose proportional at dosages from 3 to 36 mg. Peak plasma concentrations occurred 2 to 6 h after dosing. Administration with food resulted in an increase of over 30% in Cmax and in AUC. Moxidectin has a very long elimination t1/2 (mean 20–35 days) and a very large volume of distribution (Cottereau et al., 2003). Following a single dose, moxidectin was observed in the breast milk of lactating women (Korth-Bradley et al., 2011). Several hydroxy and oxidative metabolites have been identified in vitro (Dupuy et al., 2001); however, in animals the rate of metabolites is low.

**Therapeutic Uses**

Moxidectin is currently under development for the treatment of O. volvulus infections. A dose-finding phase 2 study revealed a significantly higher efficacy of 8 mg moxidectin compared to ivermectin (Awadzi et al., 2014).

**Adverse Effects**

Mazzotti reactions including pruritus, rash, increased pulse rate, and decreased mean arterial pressure were commonly observed after moxidectin treatment (Awadzi et al., 2014).

**Pediatric and Geriatric Indications and Problems.** Moxidectin has not been used in children less than 12 years of age; however, pediatric trials are ongoing.

**Levamisole**

**Chemistry**

Levamisole, the levorotatory isomer of the racemic molecule tetramisole, belongs to the imidazole derivatives. The hydrochloride salt is a white powder soluble in water but readily soluble in organic solvents.

**Mechanism of Action**

Levamisole is a cholinergic anthelminthic. The drug is a potent muscle and nerve L-subtype selective nicotinic acetylcholine receptor channel agonist. Opening of these channels produces depolarization, calcium entry, and an increase in sarcoplasmic calcium, producing spastic muscle contraction, resulting in passive elimination of the worms (Martin et al., 2012). Levamisole was also shown to inhibit fumarate reductase and hence succinate production, the main source of ATP, which is key for the survival of worms (Janssen, 1976). With regard to mammalian cells, levamisole inhibits alkaline phosphatases in most tissues (Janssen, 1976). The immunomodulatory activity of levamisole has been explained as a stimulation of antibody formation and enhancement of T cell response by stimulating T-cell activation and proliferation.

**ADME**

Levamisole is quickly absorbed from the GI tract, and Cmax levels are reached within 2 h. The drug is extensively metabolized in the liver, and its half-life is about 4 h (Janssen, 1976).

**Therapeutic Uses**

Levamisole has excellent activity against *A. lumbricoides* but low-to-moderate efficacy against *T. trichiura* and hookworm infections (Keiser and Utzinger, 2008). Levamisole has also been used for its immunomodulatory effects in cancer.

**Adverse Effects; Drug Interactions**

Adverse effects mostly occur at high dosages used for immunotherapy. At the single low dosages for anthelminthic therapy, adverse effects are minor and include nausea, vomiting, headache, dizziness, or abdominal pain. Severe adverse effects such as agranulocytosis have been described following the use of high dosages. In healthy volunteers, increased plasma levels of ivermectin and decreased plasma concentrations of albendazole sulfoxide were observed when these drugs were coadministered with levamisole (Awadzi et al., 2004).

**Nitazoxanide**

Nitazoxanide (N-[nitrothiazolyl] salicylamide) is an oral synthetic broad-spectrum antiparasitic agent. Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths). Nitazoxanide is approved in the U.S. for treatment of cryptosporidiosis and giardiasis and has activity against *E. histolytica* (see Chapter 54 for details). Nitazoxanide also has activity against intestinal helminthes such as *H. nana*, *A. lumbricoides*, *T. trichiura*, and *Entrobius vermicularis* (van den Enden, 2009). It also is an effective broad-spectrum antiviral agent (Rossignol, 2014). Adverse effects are rare with nitazoxanide.

**Acknowledgment:** Alex Loukas, James W. Tracy, and Leslie T. Webster, Jr contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Conan MacDougall

### Sulfonamides

#### HISTORY

The sulfonamide drugs were the first effective chemotherapeutic agents used systemically for the prevention and cure of bacterial infections in humans. Investigations in 1932 at the I. G. Farbenindustrie in Germany resulted in the patenting of prontosil and several other azo dyes containing a sulfonamide group. Because synthetic azo dyes had been studied for their action against streptococci, Domagk tested the new compounds and observed that mice with streptococcal septicemia and achieving a dramatic cure. Favorable clinical results with prontosil and its active metabolite, sulfanilamide, in puerperal sepsis and meningoococcal infections awakened the medical profession to the new field of antibacterial chemotherapy, and experimental and clinical articles soon appeared in profusion. The development of the carbonic anhydrase inhibitor–type diuretics and the sulfonylurea hypoglycemic agents followed from observations made with the sulfonamide antibiotics. For discovering the chemotherapeutic value of prontosil, Domagk was awarded the Nobel Prize in Medicine for 1938 (Lesch, 2007). The advent of penicillin and other antibiotics diminished the usefulness of the sulfonamides, but the introduction of the combination of trimethoprim and sulfamethoxazole in the 1970s increased the use of sulfonamides for the prophylaxis and treatment of specific microbial infections.

Sulfonamides are derivatives of para-aminobenzenesulfonamide (sulfanilamide; Figure 56–1) and are congeners of PABA. Most of them are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are all embodied in sulfanilamide itself. The sulfur must be linked directly to the benzene ring.

The para-NH₂ group (the N of which has been designated as N₄) is essential and can be replaced only by moieties that can be converted in vivo to a free amino group. Substitutions made in the amide NH group (position N₁) have variable effects on antibacterial activity of the molecule; substitution of heterocyclic aromatic nuclei at N₁ yields highly potent compounds.

#### Mechanism of Action

Sulfonamides are competitive inhibitors of dihydropteroate synthase, the bacterial enzyme responsible for the incorporation of PABA into dihydropteroic acid, the immediate precursor of folic acid (Figure 56–2). Sensitive microorganisms are those that must synthesize their own folic acid; bacteria that can use preformed folate are not affected. Sulfonamides administered as single agents are bacteriostatic; cellular and humoral defense mechanisms of the host are essential for final eradication of the infection. Toxicity is selective for bacteria because mammalian cells require preformed folic acid, cannot synthesize it, and are thus insensitive to drugs acting by this mechanism (Grayson, 2010).

#### Synergists of Sulfonamides

Trimethoprim exerts a synergistic effect with sulfonamides. It is a potent and selective competitive inhibitor of microbial dihydrofolate reductase, the enzyme that reduces dihydrofolate to tetrahydrofolate, which is required for one-carbon transfer reactions. Coadministration of a sulfonamide and trimethoprim (as in trimethoprim-sulfamethoxazole) introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate (see Figure 56–2); the combination is much more effective than either agent alone (Bushby and Hitchings, 1968). Similar complementary activity is seen with pyrimethamine, which is generally used in combination with agents such as sulfadoxine, sulfadiazine, or dapsone. The predominant systemic use of sulfonamides is now in such combinations.

#### Antibacterial Spectrum

On their original introduction to therapeutic use, sulfonamides had a wide range of antimicrobial activity against both gram-positive and
CHAPTER 56
SULFONAMIDES, TRIMETHOPRIM-SULFAMETHOXAZOLE, QUINOLONES, AND AGENTS FOR URINARY TRACT INFECTIONS

Sulfonamides

Sulfonamides are derivatives of sulfanilamide and act by virtue of being congeners of para-aminobenzoic acid (PABA). The antimicrobial and dermatological anti-inflammatory agent dapsone (4,4′-diaminodiphenyl sulphone; see Chapters 60 and 78) also bears a resemblance to PABA and sulfanilamide.

NSAID: nonsteroidal anti-inflammatory drug
PABA: para-aminobenzoic acid
PO: by mouth
TMP: trimethoprim
UTI: urinary tract infection

Bacterial Resistance

Bacterial resistance to sulfonamides can originate by random mutation and selection or by transfer of resistance by plasmids (see Chapter 52); it usually does not involve cross-resistance to other classes of antibiotics. Resistance to sulfonamide can result from (1) a lower affinity of dihydropteroate synthetase, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) increased production of an essential metabolite or drug antagonist (e.g., PABA) (Gold and Moellering, 1996). Plasmid-mediated resistance is due to plasmid-encoded, drug-resistant dihydropteroate synthetase.

ADME

Except for sulfonamides especially designed for their local effects in the bowel (see Chapter 51), this class of drugs is absorbed rapidly from the GI tract. Approximately 70%–100% of an oral dose is absorbed, and sulfonamide can be found in the urine within 30 min of ingestion. Peak plasma levels are achieved in 2–6 h, depending on the drug. Peak plasma drug concentrations achievable in vivo are about 100–200 μg/mL. The small intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. Sulfonamides are distributed throughout all tissues of the body. The sulfonamides readily enter pleural, peritoneal, synovial, ocular, and similar body fluids and may reach concentrations therein that are 50%–80% of the simultaneously determined concentration in blood. Because the protein content of body fluids usually is low, the drug is present in the unbound active form. After systemic administration of adequate doses, sulfadiazine and sulfisoxazole attain concentrations in CSF that may be effective in meningitis. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis. Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues may cause both antibacterial and toxic effects.

Sulfonamides are metabolized in the liver. The major metabolite is the N4-acetylated sulfonamide. Acetylation results in products that have no antibacterial activity but retain the toxic potential of the parent substance. Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the t1/2 depends on renal function. In acid urine, the older sulfonamides are insoluble, and crystalline deposits may form. Small amounts are eliminated in the feces, bile, milk, and other secretions.

Pharmacological Properties of Individual Sulfonamides

Sulfoxazole

Sulfoxazole is a rapidly absorbed and excreted sulfonamide. Its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides. Sulfoxazole is bound extensively to plasma proteins. Following an oral dose of 2–4 g, peak concentrations in plasma of 110–250 μg/mL are found in 2–4 h. Approximately 30% of sulfoxazole in the blood and about 30% in the urine is in the acetylated form. The kidney excretes about 95% of a single dose in 24 h. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. The concentration in CSF is about a third of that in the blood. Sulfoxazole acetyl is tasteless and hence preferred for oral use in children. Sulfoxazole acetyl in combination with erythromycin ethylsuccinate is used in children with otitis media.

The untoward effects produced by this agent are similar to those that follow the administration of other sulfonamides, as discussed further in the chapter. Because of its relatively high solubility in the urine as compared with sulfadiazine, sulfoxazole usually infrequently produces hematuria or crystalluria (0.2%–0.3%). Despite this, patients taking this drug should ingest an adequate quantity of water. Sulfoxazole currently is preferred over other sulfonamides by most clinicians when a rapidly absorbed and rapidly excreted sulfonamide is indicated.

Sulfamethoxazole

Sulfamethoxazole is a close congener of sulfoxazole, but its rates of enteric absorption and urinary excretion are slower (t1/2 of 11 h). It is administered orally and employed for both systemic and UTIs. Precautions must be observed to avoid sulfamethoxazole crystaluria because of the high percentage of the acetylated, relatively insoluble,
form of the drug in the urine. The clinical uses of sulfamethoxazole are the same as those for sulfisoxazole. In the U.S., it is marketed only in fixed-dose combinations with trimethoprim.

Sulfadiazine. Sulfadiazine given orally is absorbed rapidly from the GI tract. Peak blood concentrations are reached within 3–6 h, with a $t_{1/2}$ of 10 h. About 55% of the drug is bound to plasma protein. Therapeutic concentrations are attained in CSF within 4 h of a single oral dose of 60 mg/kg. Both free and acetylated forms of sulfadiazine are readily excreted by the kidney; 15%–40% of the excreted drug is in acetylated form. Alkalization of the urine accelerates the renal clearance of both forms by diminishing their tubular reabsorption. Precaution must be taken to ensure fluid intake adequate to produce a daily urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

Sulfadoxine. This agent has a particularly long plasma $t_{1/2}$ of 7–9 days. Although no longer marketed in the U.S., its combination with pyrimethamine (500 mg sulfadoxine plus 25 mg pyrimethamine) is listed as WHO essential medicine and is used for the prophylaxis and treatment of malaria caused by mefloquine-resistant strains of Plasmodium falciparum (see Chapter 53). However, because of severe and sometimes fatal reactions, including the Stevens-Johnson syndrome, and the emergence of resistant strains, the drug has limited usefulness for the treatment of malaria.

Sulfonamides for Topical Use

Sulfacetamide. Sulfacetamide is the N1-acetyl-substituted derivative of sulfanilamide. Its aqueous solubility is about 90 times that of sulfadiazine. Solutions of the sodium salt of the drug are employed extensively in the management of ophthalmic infections. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to sulfacetamide are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. See Chapters 69 and 70 for ocular and dermatological uses.

Silver Sulfadiazine. Silver sulfadiazine is used topically to reduce microbial colonization and the incidence of infections from burns. Silver sulfadiazine should not be used to treat an established deep infection. Silver is released slowly from the preparation in concentrations that are selectively toxic to the microorganisms. However, bacteria may develop resistance to silver sulfadiazine. Although little silver is absorbed, the plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered an agent of choice for the prevention of burn infections.

Mafenide. The sulfonamide mafenide is applied topically to prevent colonization of burns by a large variety of gram-negative and gram-positive bacteria. It should not be used in treatment of an established deep infection. Adverse effects include intense pain at sites of application and allergic reactions. Application of the drug over a large burn surface can lead to appreciable systemic absorption. The drug and its primary metabolite inhibit carbonic anhydrase, and the urine becomes alkaline. Metabolic acidosis with compensatory tachycardia and hyperventilation may ensue; these effects limit the usefulness of mafenide.

Therapeutic Uses

Urinary Tract Infections

Because a significant percentage of UTIs are caused by sulfonamide-resistant microorganisms, sulfonamides are no longer a therapy of first choice; trimethoprim-sulfamethoxazole is preferred (although resistance to this agent is increasing as well). Sulfisoxazole may be used effectively for cystitis in areas where the prevalence of resistance is not high. The usual dosage is 2–4 g initially, followed by 1–2 g orally four times a day for 5–10 days.

Nocardiosis

Trimethoprim-sulfamethoxazole is most commonly used for infections due to Nocardia spp., but sulfisoxazole or sulfadiazine are alternative agents, given in dosages of 6–8 g daily. For serious infections, addition of a second agent, such as imipenem, amikacin, or linezolid, is recommended.

Toxoplasmosis

The combination of pyrimethamine and sulfadiazine is the treatment of choice for toxoplasmosis (see Chapter 54). Pyrimethamine is given as a loading dose of 2000 mg followed by 50–75 mg orally per day, with sulfadiazine 1–1.5 g orally every 6 h, plus folic acid (leucovorin) 10–25 mg orally each day for at least 6 weeks (Panel on Opportunistic Infections, 2016). Patients should receive at least 2 L of fluid intake daily to prevent crystalluria.

Adverse Reactions

Hypersensitivity Reactions

Among the skin and mucous membrane manifestations attributed to sensitization to sulfonamide are morbilliform, scarlatinal, urticarial, erysipelas, purpura, and petechial rashes, as well as erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behcet syndrome, exfoliative dermatitis, and photosensitivity. These hypersensitivity reactions occur most often after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. The incidence of untoward dermal effects is about 2% with sulfisoxazole; patients with AIDS manifest a higher frequency of rashes with sulfonamide treatment than do other individuals. A syndrome similar to serum sickness may appear after several days of sulfonamide therapy. Drug fever is a common untoward manifestation of sulfonamide treatment; the incidence approximates 3% with sulfisoxazole.

Disturbances of the Urinary Tract

The risk of crystalluria is very low with the more soluble agents, such as sulfasuxidine. Crystalluria may be used effectively for cystitis in areas where the prevalence of resistance is not high. The usual dosage is 2–4 g initially, followed by 1–2 g orally four times a day for 5–10 days.

Disorders of the Hematopoietic System

Although rare, acute hemolytic anemia may occur. In some cases, it may be due to a sensitization phenomenon; in other instances, the hemolysis...
is related to an erythrocytic deficiency of G6PD activity. Agranulocytosis occurs in about 0.1% of patients who receive sulfadiazine; it also can follow the use of other sulfonamides. Although return of granulocytes to normal levels may be delayed for weeks or months after sulfonamide is withdrawn, most patients recover spontaneously with supportive care. Aplastic anemia involving complete suppression of bone marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. Reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with AIDS or those receiving myelosuppressive chemotherapy).

Miscellaneous Reactions
Anorexia, nausea, and vomiting occur in 1%–2% of persons receiving sulfonamides. Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in less than 0.1% of patients. Headache, nausea, vomiting, fever, hepatomegaly, jaundice, and laboratory evidence of hepatic cell dysfunction usually appear 3–5 days after sulfonamide administration is started, and the syndrome may progress to acute yellow atrophy and death. The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from plasma albumin, potentially causing an encephalopathy called kernicterus. Sulfonamides should not be given to pregnant women near term because these drugs cross the placenta and are secreted in milk.

Drug Interactions
Drug interactions of the sulfonamides are seen mainly with the oral anticoagulants, the sulfonylurea hypoglycemic agents, and the hydantoins anticonvulsants. In each case, sulfonamides can potentiate the effects of the other drug by inhibiting its metabolism or by displacing it from albumin. Dosage adjustment may be necessary when a sulfonamide is given concurrently.

Trimethoprim-Sulfamethoxazole
Trimethoprim inhibits bacterial dihydrofolate reductase, an enzyme downstream from the one that sulfonamides inhibit in the same biosynthetic sequence (see Figure 56–2). The combination of trimethoprim with sulfamethoxazole was an important advance in the development of clinically effective and synergistic antimicrobial agents. In much of the world, the combination of trimethoprim with sulfamethoxazole is known as cotrimoxazole. In addition to its combination with sulfamethoxazole, trimethoprim is available as a single-entity preparation.

Mechanism of Action
The antimicrobial activity of the combination of trimethoprim and sulfamethoxazole results from actions on sequential steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid (see Figure 56–2). Tetrahydrofolate is essential for one-carbon transfer reactions (e.g., the synthesis of thymidylate from deoxyuridylate). Selective toxicity for microorganisms is achieved in two ways. Mammalian cells use preformed folates from the diet and do not synthesize the compound. Furthermore, trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms: About 100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. The optimal ratio of the concentrations of the two agents equals the ratio of the MICs of the drugs acting independently. Although this ratio varies for different bacteria, the most effective ratio for the greatest number of microorganisms is 20:1, sulfamethoxazole:trimethoprim. The combination is thus formulated to achieve a sulfamethoxazole concentration in vivo that is 20 times greater than that of trimethoprim; sulfamethoxazole has pharmacokinetic properties such that the concentrations of the two drugs will thus be relatively constant in the body over a long period. Although each agent alone usually exerts bacteriostatic activity, when the organism is sensitive to both agents, bactericidal activity may be achieved.

Antibacterial Spectrum
The antibacterial spectrum of trimethoprim is similar to that of sulfamethoxazole, although trimethoprim is 20–100 times more potent. Pseudomonas aeruginosa, Bacteroides fragilis, and enterococci are clinically resistant. There is significant variation in the susceptibility of Enterobacteriaceae to trimethoprim in different geographic locations because of the spread of resistance mediated by plasmids and transposons (see Chapter 52).

Spectrum of Trimethoprim-Sulfamethoxazole in Combination
Although most S. pneumoniae are susceptible, there has been a disturbing increase in resistance (paralleling the rise in penicillin resistance), and its value for empiric therapy/use in respiratory tract infections is questionable. Most strains of S. aureus and Staphylococcus epidermidis remain susceptible, even among methicillin-resistant isolates, although geographic variation exists. Streptococcus pyogenes is usually sensitive when proper testing procedures (media with low thymidine content) are followed (Bowen et al., 2012). The viridans group of streptococci is typically susceptible, although susceptibility among penicillin-resistant strains is low (Diekema et al., 2001). Susceptibility in E. coli varies by geographic region, although it has been declining in general. Proteus mirabilis, Klebsiella spp., Enterobacter spp., Salmonella, Shigella, Pseudomonas pseudomallei, Serratia, and Alcaligenes spp. are typically susceptible. Also sensitive are Brucella abortus, Pasteurella haemolytica, Yersinia pseudotuberculosis, Yersinia enterocolitica, and Nocardia asteroides.

Bacterial Resistance
Bacterial resistance to trimethoprim-sulfamethoxazole is a rapidly increasing problem, although resistance is lower than it is to either of the agents alone. Resistance often is due to the acquisition of a plasmid that codes for an altered dihydrofolate reductase.

ADME
The pharmacokinetic profiles of sulfamethoxazole and trimethoprim are closely, but not perfectly, matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. After a single oral dose of the combined preparation, trimethoprim is absorbed more rapidly than sulfamethoxazole. Peak blood concentrations of trimethoprim usually occur by 2 h in most patients, whereas peak concentrations of sulfamethoxazole occur by 4 h after a single oral dose. The half-lives of trimethoprim and sulfamethoxazole are 11 and 10 h, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (one “double-strength” tablet; “single strength” ratio is 400 mg to 80 mg, maintaining the same ratio) twice daily, the peak concentrations of the drugs in plasma are about 40 and 2 μg/mL, the optimal ratio. Peak concentrations are similar (46 and 3.4 μg/mL) after intravenous infusion of 800 mg sulfamethoxazole and 160 mg trimethoprim over a period of 1 h.

Trimethoprim is distributed and concentrated rapidly in tissues; about 40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost nine times that of sulfamethoxazole. The drug readily enters CSF and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein. About 60% of administered trimethoprim and from 25% to 50% of administered sulfamethoxazole are excreted in the urine in 24 h. Two-thirds of the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

Therapeutic Uses
Urinary Tract Infections
Treatment of an uncomplicated lower UTI with trimethoprim-sulfamethoxazole is highly effective for sensitive bacteria, although some
Chemotherapy of Infectious Diseases

and infection by the intestinal parasites

ious anemias, coagulation disorders, granulocytopenia, agranulocytosis, may be relatively narrow when the patient is folate deficient. In such cases, amides. The margin between toxicity for bacteria and that for humans of the disease.

maltophilia

azole also has been used successfully for infection by trimethoprim-sulfamethoxazole (rash, neutropenia, Stevens-Johnson syndrome, Sweet syndrome, and pulmonary infiltrates). Rapid and slow desensitization protocols have been established for patients intolerant to medically necessary therapy (Gluckstein and Ruskin, 1995).

GI Infections

The combination is an alternative to a fluoroquinolone for treatment of shigellosis caused by susceptible strains, which are becoming less common worldwide. Trimethoprim and trimethoprim/sulfamethoxazole are no longer recommended for prevention or treatment of traveler’s diarrhea because of increasing resistance worldwide among likely pathogens (Hill et al., 2006).

Infection by Pneumocystis jiroveci

High-dose therapy (trimethoprim 15–20 mg/kg/d plus sulfamethoxazole 75–100 mg/kg/d in three or four divided doses; typical maximum dose is 20 mg/kg/d of trimethoprim) is effective for Pneumocystis jiroveci pneumonia (Panel on Opportunistic Infections, 2016). Adjunctive corticosteroids should be given at the onset of anti-Pneumocystis therapy in patients with a PaO2 less than 70 mm Hg or an alveolar-arterial gradient less than 35 mm Hg. Prophylaxis with 800 mg sulfamethoxazole and 160 mg trimethoprim once daily or three times a week is effective in preventing pneumonia caused by this organism in patients with HIV as well as other immunocompromising conditions (such as neutropenia and solid-organ transplantation). Adverse reactions are less frequent with the lower prophylactic doses of trimethoprim-sulfamethoxazole.

Methicillin-Resistant Staphylococcus aureus Infections

The increasing incidence of community-acquired infections due to MRSA has provided a role for trimethoprim-sulfamethoxazole as an adjunctive therapy to incision and drainage of complicated abscesses. However, it is less effective than standard therapy in the treatment of invasive MRSA infections, including bacteremia (Paul et al., 2015).

Miscellaneous Infections

Nocardia infections have been treated successfully with the combination, but failures also have been reported. Although a combination of doxycycline and streptomycin or gentamicin now is considered the treatment of choice for brucellosis, trimethoprim-sulfamethoxazole may be an effective substitute for the doxycycline combination. Trimethoprim-sulfamethoxazole also has been used successfully for infection by Stenotrophomonas maltophilia and infection by the intestinal parasites Cyclospora and Isospora. Wegener granulomatosis may respond, depending on the stage of the disease.

Adverse Effects

Trimethoprim-sulfamethoxazole may extend the toxicity of the sulfonamides. The margin between toxicity for bacteria and that for humans may be relatively narrow when the patient is folate deficient. In such cases, trimethoprim-sulfamethoxazole may cause or precipitate megaloblastosis, leukopenia, or thrombocytopenia. Hematological reactions include various anemias, coagulation disorders, granulocytopenia, agranulocytosis, purpura, Henoch-Schönlein purpura, and sulfhemoglobinemia. Trimethoprim-sulfamethoxazole reportedly causes up to three times as many dermatological reactions as does sulfisoxazole alone (5.9% vs. 1.7%). Mild and transient jaundice has been noted and appears to have the histological features of allergic cholestatic hepatitis. Permanent impairment of renal function may follow the use of trimethoprim-sulfamethoxazole in patients with renal disease due to sulfamethoxazole crystalluria; liberal fluid intake should be encouraged to dilute the urine during therapy. An increase in serum creatinine without decrement in glomerular filtration rate may be observed with high-dose therapy due to trimethoprim’s inhibition of creatinine secretion. Hyperkalemia can also be observed, as trimethoprim has a similar structure to potassium-sparing diuretics such as triamterene. Patients with HIV frequently have hypersensitivity reactions to trimethoprim-sulfamethoxazole (rash, neutropenia, Stevens-Johnson syndrome, Sweet syndrome, and pulmonary infiltrates). Rapid and slow desensitization protocols have been established for patients intolerant to medically necessary therapy (Gluckstein and Ruskin, 1995).

The Quinolones

The first quinolone, nalidixic acid, was isolated as a by-product of the synthesis of chloroquine and made available for the treatment of UTIs. The introduction of fluorinated 4-quinolones (fluoroquinolones), such as norfloxacin, ciprofloxacin, and levofloxacin (Table 56-1), represents a particularly important therapeutic advance: These agents have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases (Mitscher and Ma, 2003). However, due to potentially fatal side effects, many quinolones had to be withdrawn from the U.S. market: lomefloxacin and sparfloxacin (phototoxicity, QTc prolongation); gatifloxacin (systemic forms only; hypoglycemia); temafloxacin (immune hemolytic anemia); trovafloxacin (hepatotoxicity); grepafloxacin (cardiotoxicity); and clinafloxacin (phototoxicity). In all cases, the side effects were discovered during postmarketing surveillance (Sheehan and Chew, 2003).

Mechanism of Action

The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV. For many gram-positive bacteria, topoisomerase IV is the primary target (Alouero et al., 2000). In contrast, DNA gyrase is the primary quinolone target in many gram-negative microbes. The gyrase introduces negative supercoils into the DNA to combat excessive positive supercoiling that can occur during DNA replication (Figure 56–3) (Cozzarelli, 1980). The quinolones inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1–10 μg/mL). Mutations of the gene that encodes the A subunit of the gyrase can confer resistance to these drugs. Topoisomerase IV, which separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication, also is a target for quinolones.

Eukaryotic cells do not contain DNA gyrase. They do contain a conceptually and mechanistically similar type II DNA topoisomerase, but quinolones inhibit it only at concentrations (100–1000 μg/mL) much higher than those needed to inhibit the bacterial enzymes.

Antibacterial Spectrum

The fluoroquinolones are potent bactericidal agents against Proteus, E. coli, Klebsiella, and various species of Salmonella, Shigella, Enterobacter, and Campylobacter. While once a standard therapy for N. gonorrhoeae infections, resistance has increased to the point these agents are no longer recommended in many countries for empiric therapy of gonorrhea (Centers for Disease Control and Prevention, 2015). Some fluoroquinolones are active against Pseudomonas spp., with ciprofloxacin and levofloxacin having substantial enough activity for use in systemic infections. Fluoroquinolones have good in vitro activity against staphylococci, but they are less active against methicillin-resistant strains, and there is concern over development of resistance during therapy. Activity against streptococci is significantly greater with the newer agents, including levofloxacin,
SULFONAMIDES, TRIMETHOPRIM-SULFAMETHOXAZOLE, QUINOLONES, AND AGENTS FOR URINARY TRACT INFECTIONS

CONGENERS

Norfloxacin's gram-negative activity is similar to, but somewhat less potent than, that of ciprofloxacin. However, relatively low serum levels are reached with norfloxacin and limit its usefulness in the treatment of UTIs and gastrointestinal infections. The serum t₁/₂ is 3–5 h for norfloxacin; approximately 25% of the drug is eliminated unchanged in the urine, with hepatic metabolism also occurring.

Bacterial Resistance

Resistance to quinolones may develop during therapy via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by active transport of the drug out of the bacteria (Oethinger et al., 2000). Less commonly, plasmid-mediated resistance develops through proteins that bind to and protect the topoisomerases from quinolone effects. Resistance has increased after the introduction of fluoroquinolones, especially in Pseudomonas and staphylococci. Escherichia coli, Campylobacter jejuni, Salmonella, N. gonorrhoeae, and S. pneumoniae are also increasingly fluoroquinolone resistant (Olson et al., 2009).

ADME

Most quinolones are well absorbed after oral administration. Peak serum levels of the fluoroquinolones are obtained within 1–3 h of an oral dose. The volume of distribution of quinolones is high, with concentrations in urine, kidney, lung, and prostate tissue and stool, bile, and macrophages and neutrophils higher than serum levels. Food may delay the time to peak serum concentrations. Ciprofloxacin, ofloxacin, and levofloxacin have been detected in human breast milk; because of their excellent bioavailability, the potential exists for substantial exposure of nursing infants. Except for moxifloxacin, quinolones are cleared predominantly by the kidney, and dosages must be adjusted for renal failure. Moxifloxacin should not be used in patients with hepatic failure.

Pharmacological Properties of Individual Quinolones

Norfloxacin

Norfloxacin's gram-negative activity is similar to, but somewhat less potent than, that of ciprofloxacin. However, relatively low serum levels are reached with norfloxacin and limit its usefulness in the treatment of UTIs and gastrointestinal infections. The serum t₁/₂ is 3–5 h for norfloxacin; approximately 25% of the drug is eliminated unchanged in the urine, with hepatic metabolism also occurring.

Ciprofloxacin

Ciprofloxacin's bioavailability is approximately 70%. Typical oral doses are 250–750 mg and intravenous doses are 200–400 mg twice daily (maximum dose 1.5 g/d). The elimination t₁/₂ is about 5 h, and the drug is typically dosed twice daily, with the exception of an extended-release formulation, which can be dosed once daily.

Ofloxacin/Levofloxacin

Ofloxacin has somewhat more potent gram-positive activity; separation of the more active S- or levorotatory isomer yields levofloxacin, which has even better antistreptococcal activity. Bioavailability of both of these agents is excellent, such that intravenous and oral doses are the same; levofloxacin is dosed once daily (250–750 mg) as opposed to twice-daily dosing for ofloxacin (200–400 mg daily divided every 12 h).

Moxifloxacin

Moxifloxacin improves further on the gram-positive potency of levofloxacin, typically having MICs one to two dilutions lower against gemifloxacin, and moxifloxacin. Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of Chlamydia, Mycoplasma, Legionella, Brucella, and Mycobacterium (including Mycobacterium tuberculosis). Ciprofloxacin, ofloxacin, and moxifloxacin have MIC₉₀ values from 0.5 to 3 μg/mL for Mycobacterium fortuitum, Mycobacterium kansasii, and M. tuberculosis. Moxifloxacin also has useful activity against anaerobes.

Figure 56–3 Model of the formation of negative DNA supercoils by DNA gyrase. DNA gyrase binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (−) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and, at higher concentrations, block the decatenating activity of topoisomerase IV. (Reprinted with permission from AAAS. Cozzarelli NR. DNA gyrase and the supercoiling of DNA. Science, 1980, 207:953–960.)
S. pneumoniae. It also has expanded activity against anaerobic pathogens but is substantially less active than ciprofloxacin or levofloxacin against P. aeruginosa. Moxifloxacin is well absorbed, with equivalent intravenous and oral doses; the t1/2 is about 12 h, allowing for daily dosing (usual dose 400 mg daily). Moxifloxacin undergoes hepatic sulfation and glucuronidation. Less than a quarter of systemic moxifloxacin is excreted unchanged via the kidneys, and because high concentrations are not achieved in the urine, it is not recommended for UTIs.

**Gatifloxacin and Gemifloxacin**

The agents gatifloxacin and gemifloxacin have a similar spectrum of activity to moxifloxacin, with enhanced potency against gram-positive organisms and poor activity versus *Pseudomonas*. They are less active than moxifloxacin against *B. fragilis*. Both have high bioavailability and renal elimination. Gatifloxacin is no longer available for systemic use in the U.S. due to toxicity concerns, but an ophthalmic preparation is licensed for the treatment of bacterial conjunctivitis.

**Therapeutic Uses**

**Urinary Tract Infections**

Nalidixic acid is useful only for UTIs caused by susceptible microorganisms. The fluoroquinolones are significantly more potent and are a mainstay of treatment of upper and lower UTIs (Pihm, 2003). They are more efficacious than trimethoprim-sulfamethoxazole or oral β-lactams for the treatment of UTIs. Because of their broad spectrum of activity, however, recent guidelines suggest reserving their use for complicated cystitis or pyelonephritis only. Moxifloxacin does not accumulate in the urine and is not approved for treatment of UTIs. Typical treatment durations for the other quinolones are 3 days for uncomplicated cystitis and 5–7 days for uncomplicated pyelonephritis.

**Prostatitis**

Norfloxacin, ciprofloxacin, ofloxacin, and levofloxacin are effective in the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4–6 weeks appear to be effective in patients not responding to trimethoprim-sulfamethoxazole.

**Sexually Transmitted Diseases**

Fluoroquinolones lack activity for *Treponema pallidum* but have activity in vitro against *Chlamydia trachomatis* and Haemophilus ducreyi. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin or levofloxacin is an alternative to a 7-day treatment with doxycycline or a single dose of azithromycin; other available quinolones have not been reliably effective. Previously, a single oral dose of a fluoroquinolone such as ciprofloxacin had been effective treatment of sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has led to ceftriaxone being the first-line agent for this infection. Chancroid (infection by *H. ducreyi*) can be treated with 3 days of ciprofloxacin.

**GI and Abdominal Infections**

Norfloxacin, ciprofloxacin, ofloxacin, and levofloxacin given for 1–3 days all have been effective in the treatment of patients with traveler's diarrhea, reducing the duration of loose stools by 1–3 days. Ciprofloxacin in a single daily dose is also effective for prophylaxis of traveler's diarrhea. Ciprofloxacin and ofloxacin can cure most patients with enteric fever caused by *Salmonella typhi*, as well as bacteremic nontyphoidal infections in patients with HIV, and clears chronic fecal carriage. Ciprofloxacin, ofloxacin, and levofloxacin, when combined with metronidazole, may be useful in the management of intra-abdominal infections when *Enterococcus* is not a likely pathogen. Moxifloxacin as a single agent was shown to have similar efficacy to piperacillin/tazobactam for complicated intra-abdominal infections, although there are concerns over increasing resistance in *B. fragilis*.

**Respiratory Tract Infections**

Many newer fluoroquinolones, including levofloxacin, moxifloxacin, and gemifloxin, have excellent activity against *S. pneumoniae*, *H. influenzae*, and the atypical respiratory pathogens. Thus, these agents are frequently used in the management of community-acquired pneumonia and for upper respiratory tract infections such as sinusitis that are not responsive to more narrow-spectrum agents. Mild-to-moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis have responded to oral fluoroquinolone therapy with ciprofloxacin or levofloxacin.

**Bone, Joint, and Soft Tissue Infections**

The treatment of chronic osteomyelitis may require prolonged (weeks to months) antimicrobial therapy with agents active against *S. aureus* or gram-negative rods. Failures are associated with the development of resistance, particularly in *S. aureus*. Combination therapy with a fluoroquinolone and rifampin has been effective at reducing the development of resistance and providing good cure rates, especially in the management of early prosthetic joint infections. In diabetic foot infections, the fluoroquinolones in combination with an agent with antianaerobic activity are a reasonable choice.

**Other Infections**

Ciprofloxacin and levofloxacin are used for the prophylaxis of anthrax and are effective for the treatment of tularemia (Hendricks et al., 2014). The quinolones, especially moxifloxacin, may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and atypical mycobacterial infections as well as *Mycobacterium avium* complex infections in AIDS (see Chapter 60) (American Thoracic Society, 2003). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias (Hughes et al., 2002). Levofloxacin and ciprofloxacin are approved to treat and prevent anthrax as well as plague due to *Yersinia pestis*.

**Adverse Effects**

**Gastrointestinal Adverse Effects**

Common adverse reactions involve the GI tract, with 3%–17% of patients reporting mild nausea, vomiting, and abdominal discomfort. Fluoroquinolones have emerged as a common cause of *Clostridium difficile* colitis due to the spread of quinolone-resistant strains.

**Neurologic Adverse Effects**

Side effects (1%–11%) of the CNS include mild headache and dizziness. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who were also receiving theophylline or NSAIDs. Patients with a history of epilepsy are at higher risk for fluoroquinoline-induced convulsions. Recently, the fluoroquinolones have been recognized as a rare cause of peripheral neuropathy, which in some cases has been irreversible.

**Musculoskeletal Adverse Effects**

Arthralgias and joint pain are occasionally reported with fluoroquinolones. Tendon rupture or tendinitis (usually of the Achilles tendon) is a recognized adverse effect, especially in those more than 60 years old, in patients taking corticosteroids, and in solid-organ transplant recipients. Early animal studies suggested an increased risk of cartilage damage and malformation among young animals (Burkhardt et al., 1997). Subsequent human studies have not noted a substantially increased risk of these effects in children or among the offspring of pregnant women who received fluoroquinolones. Nevertheless, the agents are typically avoided in pregnancy and among young children (Sahbarwal and Marchant, 2006).

**Other Adverse Effects**

Among the quinolones available in the U.S., moxifloxacin carries the highest risk for QT interval prolongation and torsades de pointes arrhythmias; gemifloxacin, levofloxacin, and ofloxacin appear to have lower risk; and ciprofloxacin has the lowest risk. However, the overall risk of torsades de pointes is small with the use of fluoroquinolones. Gatifloxacin's propensity to cause both hypo- and hyperglycemia, especially in older adults, led to its removal for systemic use in the U.S. (Park-Wyllie et al., 2006). Other agents such as levofloxacin may rarely be associated with dysglycemias among at-risk patients. Rashes, including photosensitivity reactions, also can occur; patients with frequent sun exposure should be advised to protect themselves with clothing or sunscreen.
Drug Interactions

All quinolones form complexes with divalent and trivalent cations (e.g., calcium, iron, aluminum). When coadministered orally with quinolones, these cations can chelate the quinolone and reduce systemic bioavailability. Thus, a separation of at least 2 h between oral administration of quinolones and these cations is recommended. Ciprofloxacin inhibits the metabolism of theophylline, and toxicity from elevated concentrations of the methylxanthine may occur (Schwartz et al., 1988). NSAIDs may augment displacement of GABA from its receptors by the quinolones, enhancing neurologic adverse effects (Halliwell et al., 1993). Due to risk for QT prolongation, quinolones should be used with caution in patients on class III (amiodarone) and class IA (quinidine, procainamide) antiarrhythmics (see Chapter 30).

Antiseptic Agents for Urinary Tract Infections

Urineal tract antiseptics are concentrated in the renal tubules, where they inhibit the growth of many species of bacteria. These agents cannot be used to treat systemic infections because effective concentrations are not achieved in plasma with safe doses; however, they can be administered orally to treat UTIs.

Methenamine

Methenamine (hexamethylenamine) is a urinary tract antiseptic and prodrug that acts by generating formaldehyde via the following reaction:

$$\text{N}_2\left(\text{CH}_3\right)_6 + 6\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 6\text{HCHO} + 4\text{NH}_3^+$$

At pH 7.4, almost no decomposition occurs; the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes formaldehyde formation and formaldehyde-dependent antibacterial action. The decomposition reaction is fairly slow, and 3 h are required to reach 90% completion.

Antimicrobial Activity

Naturally all bacteria are sensitive to free formaldehyde at concentrations of about 20 μg/mL. Microorganisms do not develop resistance to formaldehyde. Urea-splitting microorganisms (e.g., Proteus spp.) tend to raise the pH of the urine and thus inhibit the release of formaldehyde.

Pharmacology, Toxicity, and Therapeutic Uses

Methenamine is absorbed orally, but 10%–30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, methenamine is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000–1500 mL, a daily dose of 2 g will yield a urine concentration of 18–60 μg/mL of formaldehyde; this is more than the MIC for most urinary tract pathogens. Low pH alone is bacteriostatic, so acidification serves a double function. The acids commonly used are mandelic acid and hippuric acid. GI distress frequently is caused by doses more than 500 mg four times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/d given for longer than 3–4 weeks. Renal insufficiency is not a contraindication to the use of methenamine alone, but the acids given concurrently may be detrimental; methenamine mandelate is contraindicated in renal insufficiency. Methenamine combines with sulfamethizole and perhaps other sulfonamides in the urine, which results in mutual antagonism; therefore, these drugs should not be used in combination.

Methenamine is not a primary drug for the treatment of acute UTIs but is of value for chronic suppressive treatment of UTIs. The agent is most useful when the causative organism is E. coli, but it usually can suppress the common gram-negative offenders and often S. aureus and S. epidermidis as well. Enterobacter aerogenes and Proteus vulgaris are usually resistant. A urinary pH less than 5 is typically necessary for methenamine to be active; some clinicians recommend monitoring of the urinary pH and even urinary acidification with ammonium chloride or ascorbic acid.

Nitrofurantoin

Nitrofurantoin is a synthetic nitrofuran that is used for the prevention and treatment of UTIs.

Antimicrobial Activity

Nitrofurantoin is activated by enzymatic reduction, with the formation of highly reactive intermediates that seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce nitrofurantoin more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. Nitrofurantoin is active against many strains of E. coli and enterococci. However, most species of Proteus and Pseudomonas and many species of Enterobacter and Klebsiella are resistant. Nitrofurantoin is bacteriostatic for most susceptible microorganisms at concentrations of 32 μg/mL or less and is bactericidal at concentrations of 100 μg/mL or more. The antibacterial activity is higher in acidic urine.

Pharmacology, Toxicity, and Therapeutic Uses

Nitrofurantoin is absorbed rapidly and completely from the GI tract. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly. The plasma t1/2 is 0.3–1 h; about 40% is excreted unchanged into the urine. The average dose of nitrofurantoin yields a concentration in urine of about 200 μg/mL. This concentration is soluble at pH greater than 5, but the urine should not be alkalized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance, so in patients with impaired glomerular function, the efficacy of the drug may be decreased and the systemic toxicity increased. Nitrofurantoin colors the urine brown.

The oral dosage of nitrofurantoin for adults is 50–100 mg four times a day with meals and at bedtime, less for the macrocrystalline formulation (100 mg every 12 h for 7 days). A single 50–to 100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5–7 mg/kg but may be as low as 1 mg/kg for long-term therapy. A course of therapy should not exceed 14 days; repeated courses should be separated by rest periods. Pregnant women, individuals with impaired renal function (creatinine clearance less than 60 mL/min), and children younger than 1 month should not receive nitrofurantoin.

Nitrofurantoin is approved for the treatment of lower UTIs. It is not recommended for treatment of pyelonephritis or prostatitis.

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated than traditional formulations. Various hypersensitivity reactions occur occasionally, including chills, fever, leukopenia, granulocytopenia, hemolytic anemia (associated with G6PD deficiency and in newborns exhibiting low levels of reduced glutathione in their red blood cells), cholestatic jaundice, and hepatocellular damage. Acute pneumonitis with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. Intestinal pulmonary fibrosis can occur in patients (especially the elderly) taking the drug chronically. Headache, vertigo, drowsiness, muscular aches, and nystagmus occur occasionally but are readily reversible. Severe polyneuropathies with demyelination and degeneration of both sensory and motor nerves have been reported; neuropathies are most likely to occur in patients with impaired renal function and in persons on long-continued treatment.

Fosfomycin

Fosfomycin is a phosphonic acid derivative that is used primarily for the prevention and treatment of UTIs.

Antimicrobial Activity

Fosfomycin inhibits MurA, an enolpyruvyl transferase that catalyzes the initial step in bacterial cell wall synthesis. This mechanism is unique among antibacterials; thus, cross-resistance to other agents is rarely seen. Optimal testing of fosfomycin activity requires supplementation of the media with glucose-6-phosphate. Fosfomycin’s usual spectrum of activity
includes the uropathogens *E. coli*, *Proteus*, *Enterococcus*, and *Staphylococcus saprophyticus*. Activity against *Klebsiella*, *Enterobacter*, and *Serratia* spp. is variable, and *Pseudomonas* and *Acinetobacter* are typically resistant. *Staphylococcus aureus* is frequently susceptible, although emergence of resistance during therapy has been reported.

**Pharmacology, Toxicity, and Therapeutic Uses**

Outside the U.S., fosfomycin is available as an intravenous formulation that can achieve adequate levels to treat some systemic infections. However, in the U.S. it is only available as a powder (fosfomycin tromethamine) that is dissolved in water and taken orally. Bioavailability of the oral formulation is approximately 40%, with a $t_{1/2}$ of 5–8 h. With oral administration of 3 g, systemic concentrations are low, but urinary concentrations are as high as 1000–4000 μg/mL. The FDA-approved dosing regimen is a single 3-g dose for uncomplicated UTI; some investigators have administered 3 g every other day for three doses for complicated UTI or 3 g every 10 days for UTI prophylaxis.

Overall, fosfomycin is well tolerated. Adverse effects are uncommon and usually consist of GI distress, vaginitis, headache, or dizziness.

**Acknowledgment:** William A. Petri, Jr contributed to this chapter in the previous editions of this book. We have retained some of his text in the current edition.

Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents. Guidelines for the prevention and treatment of opportunistic infections in HIV-infected adults and adolescents: recommendations from the Centers for Disease Control and Prevention, the National Institutes of...

The β-lactam antibiotics—*penicillins, cephalosporins, carbapenems,* and *monobactams*—share a common structure (β-lactam ring) and mechanism of action (i.e., inhibition of the synthesis of the bacterial peptidoglycan cell wall). Bacterial resistance against the β-lactam antibiotics continues to increase at a dramatic rate. β-Lactamase inhibitors such as clavulanate and avibactam can extend the utility of these antibiotics against β-lactamase-producing organisms. Unfortunately, resistance includes not only production of β-lactamases but also alterations in the bacterial enzymes targeted by β-lactam antibiotics, as well as decreased entry or active efflux of the antibiotic.

Mechanism of Action: Inhibition of Peptidoglycan Synthesis

Peptidoglycan is a heteropolymERIC component of the bacterial cell wall that provides rigid mechanical stability. The β-lactam antibiotics inhibit the last step in peptidoglycan synthesis (Figure 57–1).

In gram-positive microorganisms, the cell wall is 50–100 molecules thick; in gram-negative bacteria, it is only 1 or 2 molecules thick (Figure 57–2A). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (N-acetylmuramic acid and N-acetylgulosamine) that are cross-linked by peptide chains. Peptidoglycan precursor formation takes place in the cytoplasm. The synthesis of UDP-acetylmuramyl-pentapeptide is completed with the addition of a dipeptide, N-alanyl-D-alanine (formed by racemization and condensation of L-alanine). UDP-acetylmuramyl-pentapeptide and UDP-acetylgulosamine are linked (with the release of the uridine nucleotides) to form a long polymer. The cross-link is completed by a transpeptidation reaction that occurs outside the cell membrane (Figure 57–2B).

The β-lactam antibiotics inhibit this last step in peptidoglycan synthesis (see Figure 57–1), presumably by acylating the transpeptidase via cleavage of the –CO-N– bond of the β-lactam ring. The targets for the actions of β-lactam antibiotics are collectively termed PBPs. The transpeptidase responsible for synthesis of the peptidoglycan is one of these PBPs.

The lethality of penicillins for bacteria appears to involve both lytic and nonlytic mechanisms (Bayles, 2000).

Mechanisms of Bacterial Resistance to Penicillins and Cephalosporins

Bacteria can be resistant to β-lactam antibiotics by myriad mechanisms. A sensitive strain may acquire resistance by mutations that decrease the affinity of PBPs for the antibiotic. Because the β-lactam antibiotics inhibit many different PBPs in a single bacterium, the affinity for β-lactam antibiotics of several PBPs must decrease for the organism to be resistant (Spratt, 1994). Altered PBPs with decreased affinity for β-lactam antibiotics are acquired by homologous recombination between PBP genes of different bacterial species (Zapun et al., 2008). Four of the five high-molecular-weight PBPs of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β-lactam antibiotics as a result of interspecies homologous recombination events. In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only two of the five high-molecular-weight PBPs because the other PBPs have inherently low affinity for the third-generation cephalosporins. MRSA is resistant via acquisition of an additional high-molecular-weight PBP (via a transposon) with a very low affinity for all β-lactam antibiotics; this mechanism is also responsible for methicillin resistance in the coagulase-negative staphylococci.

Bacterial resistance to the β-lactam antibiotics also results from the inability of the agent to penetrate to its site of action (Figure 57–3) (Fernández and Hancock, 2012). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (see Figure 57–2A) and small β-lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the PBPs. In gram-negative bacteria, the inner membrane is covered by the outer membrane, lipopolysaccharide, and capsule (see Figure 57–2A). The outer membrane functions as an impermeable barrier for some antibiotics. Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that...
Staphylococcus aureus. The penicillins and ampicillin are less active than piperacillin and its close congener (Figures 57–2 and 57–4). β-Lactamases are highly active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase. Similarly, bacteria that survive inside viable cells of the host generally are protected from the action of the β-lactam antibiotics.

Despite the emergence of microbial resistance, the penicillins are currently the drugs of choice for a large number of infectious diseases. Penicillins (Figure 57–4) consist of a thiazolidine ring (A) connected to a β-lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself is the chief structural requirement for biological activity. Side chains can be added that alter the susceptibility of the resulting compounds to inactivating enzymes (β-lactamases) and that change the antibacterial activity and the pharmacological properties of the drug (Table 57–1).

Classification of the Penicillins and Summary of Their Pharmacological Properties

Penicillins are classified according to their spectra of antimicrobial activity.

- **Penicillin G** and its close congener **penicillin V** are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinase. Thus, they are ineffective against most strains of *S. aureus*.
- The **penicillinase-resistant penicillins** (methicillin, discontinued in the U.S.), cloxacillin and flucloxacillin (not currently marketed in the U.S.), nafcillin, oxacillin, and dicloxacillin have less-potent antimicrobial activity against microorganisms that are sensitive to penicillin G, but they are preferred agents for treatment of penicillinase-producing *S. aureus* and Staphylococcus epidermidis that are not methicillin resistant.
- Ampicillin, amoxicillin, and others such as bacampicillin and pivampicillin (not currently marketed in the U.S.) are the **aminopenicillins**, whose antimicrobial activity is extended to include some gram-negative microorganisms (e.g., *Haemophilus influenzae*, Escherichia coli, and *Proteus mirabilis*). These drugs are also available as coformulations with a β-lactamase inhibitor such as clavulanate or sulbactam to prevent hydrolysis by class A β-lactamases.
- **Agents with extended antimicrobial activity against Pseudomonas, Enterobacter, and Proteus spp.** include older agents largely out of use: azlocillin, carbenicillin, mezlocillin, ticarcillin, ticarcillin/ clavulanate (all discontinued in the U.S.), and carbenicillin indanyl sodium. These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin.
CHEMOTHERAPY OF INFECTIOUS DISEASES

SECTION VII

CHEMOTHERAPY OF INFECTIOUS DISEASES

Figure 57–3  Antibiotic efflux pumps of gram-negative bacteria. Multidrug efflux pumps traverse both the inner and outer membranes of gram-negative bacteria. The pumps are composed of a minimum of three proteins and are energized by the proton motive force. Increased expression of these pumps is an important cause of antibiotic resistance. (Reprinted with permission from Oxford University Press. Nikaido H. Antibiotic resistance caused by gram-negative multidrug efflux pumps. Clin Infect Dis, 1998, 27(suppl 1): S32–S41. © 1998 by the Infectious Diseases Society of America. All rights reserved.)

Piperacillin and piperacillin/tazobactam have excellent antimicrobial activity against many isolates of Pseudomonas, E. coli, Klebsiella, and other gram-negative microorganisms. Piperacillin retains the activity of ampicillin against gram-positive cocci and L. monocytogenes.

Figure 57–2  A. Structure and composition of gram-positive and gram-negative cell walls. B. PBP activity and inhibition. PBPs have two enzymatic activities that are crucial to synthesis of the peptidoglycan layers of bacterial cell walls: a TP that cross-links amino acid side chains and a GT that links subunits of the glycopeptide polymer (see Figure 57–1). The TP and GT domains are separated by a linker region. The glycosyltransferase is thought to be partially embedded in the membrane. (Part A reprinted with permission from Tortora G, et al. Microbiology: An Introduction, 3rd ed. Pearson, London, 1989, Figure 4–11, p. 83. © Pearson Education, Inc., New York, New York.)

General Common Properties

Following absorption of an oral dose, penicillins are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in CSF are variable but are less than 1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly by glomerular filtration and renal tubular secretion, such that their half-lives in the body are short, typically 30–90 min. As a consequence, concentrations of these drugs in urine are high.

Penicillin G and Penicillin V

Antimicrobial Activity

The antimicrobial spectra of penicillin G (benzylpenicillin) and penicillin V (the phenoxymethyl derivative) are similar for aerobic gram-positive microorganisms. However, penicillin G is 5–10 times more active than penicillin V against Neisseria spp. and certain anaerobes. Most streptococci are very susceptible. However, penicillin-resistant viridans streptococci
and *S. pneumoniae* are becoming more common (Carratalá et al., 1995). Penicillin-resistant pneumococci are especially common in pediatric populations and are often also resistant to third-generation cephalosporins. Greater than 90% of strains of *S. aureus*, most strains of *S. epidermidis*, and many strains of gonococci are now resistant to penicillin G. With rare exceptions, meningococci remain quite sensitive to penicillin G.

Most anaerobic microorganisms, including *Clostridium* spp., are highly sensitive. *Bacteroides fragilis* is an exception, displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Some strains of *Prevotella melaninogenicus* also have acquired this trait. *Actinomyces israelii*, *Streptobacillus moniliformis*, *Pasteurella multocida*, and *L. monocytogenes* are inhibited by penicillin G. Most species of *Leptospira* are moderately susceptible to the drug. One of the most sensitive microorganisms is *Treponema pallidum*. *Borrelia burgdorferi*, the organism responsible for Lyme disease, also is susceptible. Penicillins are not effective against amebae, plasmodia, rickettsiae, fungi, or viruses.

**ADME**

**Oral Administration of Penicillin G and V.** The virtue of penicillin V in comparison with penicillin G is that it is more stable in an acidic medium and therefore is better absorbed from the GI tract, yielding plasma concentrations two to five times those provided by penicillin G. Thus, penicillin V is generally preferred for oral administration. Absorption is rapid, and maximal concentrations in blood are attained in 30–60 min. Ingestion of food may interfere with enteric absorption of all penicillins. Thus, oral penicillins should generally be administered at least 30 min before a meal or 2 h after.

**Parenteral Administration of Penicillin G.** After intramuscular injection, peak concentrations in plasma are reached within 15–30 min, declining rapidly thereafter ($t_{1/2} – 30$ min). Repository preparations of penicillin G (penicillin G benzathine, penicillin G procaine) increase the duration of the effect. The compound currently favored is penicillin G benzathine, which releases penicillin G slowly from the area in which it is injected and produces relatively low but persistent concentrations in the blood. The average duration of demonstrable antimicrobial activity in the plasma is about 26 days. It is administered once monthly for rheumatic fever prophylaxis and can be given in a single injection to treat streptococcal pharyngitis. Penicillin G procaine has a prolonged $t_{1/2}$ compared to penicillin G, but shorter than that of benzathine formulations; it is typically dosed once daily. Neither depot formulation should be given intravenously as serious toxicity can result.

**Distribution.** Penicillin G is distributed extensively throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is about 0.35 L/kg. Approximately 60% of the penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine. Probenecid markedly decreases the tubular secretion of the penicillins and also produces a significant decrease in the apparent volume of distribution of the penicillins.

**Penetration Into Cerebrospinal Fluid.** Penicillin does not readily enter the CSF but penetrates more easily when the meninges are inflamed. The concentrations are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms. Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. Probenecid competitively inhibits this transport and thus elevates the concentration of penicillin in CSF. In uremia, other organic acids accumulate in the CSF and compete with penicillin for secretion; the drug occasionally reaches toxic concentrations in the brain and can produce convulsions.
**HISTORY**

The history of the brilliant research that led to the discovery and development of penicillin is well chronicled (Lax, 2004). In 1928, while studying *Staphylococcus* variants in the laboratory at St. Mary’s Hospital in London, Alexander Fleming observed that a mold contaminating one of his cultures caused the bacteria in its vicinity to undergo lysis. Broth in which the fungus was grown was markedly inhibitory for many microorganisms. Because the mold belonged to the genus *Penicillium*, Fleming named the antibacterial substance *penicillin*.

A decade later, penicillin was developed as a systemic therapeutic agent by the concerted research of a group of investigators at Oxford University headed by Florey, Chain, and Abraham. By May 1940, a crude preparation was found to produce dramatic therapeutic effects when administered parenterally to mice with streptococcal infections. Sufficient penicillin was accumulated by 1941 to conduct therapeutic trials in several patients desperately ill with staphylococcal and streptococcal infections refractory to all other therapy. At this stage, the crude, amorphous penicillin was only about 10% pure, and it required nearly 100 L of the broth in which the mold had been grown to obtain enough of the antibiotic to treat one patient for 24 h. Bedpans actually were used by the Oxford group for growing cultures of *Penicillium notatum*. Case 1 in the 1941 report from Oxford was that of a policeman who was suffering from a severe mixed staphylococcal and streptococcal infection. He was treated with penicillin, some of which had been recovered from the urine of other patients who had been given the drug. It is said that an Oxford professor referred to penicillin as a remarkable substance grown in bedpans and purified by passage through the Oxford Police Force.

A vast research program soon was initiated in the U.S. There were 122 million units of penicillin made available during 1942, and the first clinical trials were conducted at Yale University and the Mayo Clinic, with dramatic results. By the spring of 1943, there were 200 patients who had been treated with the drug. The results were so impressive that the surgeon general of the U.S. Army authorized a trial of the antibiotic in a military hospital. Soon thereafter, penicillin was adopted throughout the medical services of the U.S. Armed Forces.

The deep-fermentation procedure for the biosynthesis of penicillin marked a crucial advance in the large-scale production of the antibiotic. From a total production of a few hundred million units a month in the early days, the quantity manufactured rose to over 200 trillion units (nearly 150 tons) by 1950. The first marketable penicillin cost several dollars per 100,000 units; today, the same dose costs only a few cents.

**Excretion.** Approximately 60%–90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid (see Figure 57–4). The $t_{1/2}$ for elimination of penicillin G is about 30 min in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. Clearance values are considerably lower in neonates and infants; as a result, penicillin persists in the blood several times longer in premature infants than in children and adults. The $t_{1/2}$ of the antibiotic in children less than 1 week of age is 3 h; by 14 days of age, it is 1.4 h. After renal function is fully established in young children, the rate of renal excretion of penicillin G is considerably more rapid than in adults. Anuria increases the $t_{1/2}$ of penicillin G from 0.5 to about 10 h. When renal function is impaired, 7%–10% of the antibiotic may be inactivated each hour by the liver. The dose of the drug must be readjusted during dialysis and the period of progressive recovery of renal function. If hepatic insufficiency also is present, the $t_{1/2}$ will be prolonged even further.

**Therapeutic Uses**

**Pneumococcal Infections.** Penicillin G remains the agent of choice for the management of infections caused by sensitive strains of *S. pneumoniae*, but resistance is an increasing problem.

**Pneumococcal Pneumonia.** For parenteral therapy of sensitive isolates of pneumococci, penicillin G is favored. Therapy should be continued for at least 5 days, including at least 2–3 days after the patient's temperature has returned to normal.

**Pneumococcal Meningitis.** Pneumococcal meningitis should be treated with a combination of vancomycin and a third-generation cephalosporin until it is established that the infecting pneumococcus is penicillin-sensitive. Dexamethasone given prior to or at the same time as antibiotics is associated with an improved outcome (de Gans et al., 2002). The recommended therapy is 24 million units of penicillin G daily by constant intravenous infusion or divided into boluses for 10–14 days.

**β-Hemolytic Streptococcal Infections.** *Streptococcus pharyngitis* (including *scarlet fever*) is the most common disease produced by *Streptococcus pyogenes* (group A β-hemolytic streptococcus). Penicillin-resistant isolates have yet to be observed. The preferred oral therapy is with penicillin V, 500 mg twice daily for 10 days. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with penicillin (Shulman et al., 2012).

**β-Hemolytic Streptococcal Toxic Shock and Necrotizing Fasciitis.** β-Hemolytic streptococcal toxic shock and necrotizing fasciitis are life-threatening infections associated with toxin production. Recommended treatment is with penicillin plus clindamycin (to decrease toxin production) (Brown, 2004).

**β-Hemolytic Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis.** The uncommon conditions of pneumonia, arthritis, meningitis, and endocarditis caused by β-hemolytic streptococci should be treated with penicillin G when they are caused by *S. pyogenes*; daily doses of 12–24 million units are administered intravenously for 2–4 weeks (4 weeks for endocarditis).

**Infections Caused by Other Streptococci and Enterococci.** The viridans group of streptococci is the most common cause of native valve infections and endocarditis. These are nongroupable α-hemolytic microorganisms that are increasingly resistant to penicillin G. It is important to determine quantitative microbial sensitivities to penicillin G in patients with endocarditis. Patients with penicillin-sensitive viridans group streptococcal native valve endocarditis can be treated successfully with daily doses of 12–20 million units of intravenous penicillin G for 4 weeks or for 2 weeks if given in combination with gentamicin. The recommended therapy for penicillin- and amoxicillin-sensitive enterococcal endocarditis is 24 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with a low dose of gentamicin. Therapy usually should be continued for 6 weeks.

**Infections with Anaerobes.** Pulmonary and periodontal infections usually respond well to penicillin G; clindamycin may be more effective than penicillin for therapy of lung abscess (Levison et al., 1983). Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 250 mg four times daily). More severe infections should be treated with 12–24 million units of penicillin G intravenously.

**Staphylococcal Infections.** Most staphylococcal infections are caused by microorganisms that produce penicillinase; further, half or more isolates of *S. aureus* and *S. epidermidis* are resistant to β-lactams through production of altered PBPs. Thus, penicillin G now has limited utility in the treatment of staphylococcal infections.

**Meningococcal Infections.** Penicillin G remains the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously. The occurrence of penicillin-resistant strains...
should be considered in patients who are slow to respond to treatment. Penicillin G does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure.

**Gonococcal Infections.** Gonococci gradually have become more resistant to penicillin G, and penicillins are no longer the therapy of choice.

**Syphilis.** Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of less than 1 year duration may be treated with 1–3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine. Patients with neurosyphilis or cardiovascular syphilis daily for 10–14 days. There are no proven alternatives for treating syphilis in pregnant women, so penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis.

Most patients with secondary syphilis develop the Jarisch-Herxheimer reaction, including chills, fever, headache, myalgias, and arthralgias occurring several hours after the first dose of penicillin. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. Antipyretics give symptomatic relief, and therapy with penicillin should not be discontinued.

**Actinomycosis.** Penicillin G is the agent of choice for the treatment of all forms of actinomycosis (18–24 million units of penicillin G IV per day for 6 weeks). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

**Diphtheria.** Penicillin and other antibiotics do not alter the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. However, penicillin G eliminates the carrier state. The parenteral administration of 2–3 million units per day in divided doses for 10–12 days eliminates the diphtheria bacilli from the pharynx and other sites in practically 100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

**Anthrax.** Strains of *Bacillus anthracis* resistant to penicillin have been recovered from human infections. When penicillin G is used for serious infections due to susceptible strains, the dose should be 24 million units per day.

**Clostridial Infections.** Penicillin G (12–24 million units per day given parenterally) plus clindamycin is recommended for clostridial gas gangrene. Adequate debridement of the infected areas is essential. Antibiotics probably have no effect on the outcome of tetanus. Debridement and administration of human tetanus immune globulin may be indicated.

**Fusariospore infections.** Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and spirochetes that are present in the mouth, is readily treatable with penicillin. For simple “trench mouth,” 500 mg penicillin V given every 6 h for several days usually suffices.

**Rat-Bite Fever.** The two microorganisms responsible for the rat-bite fever infection, *Spirillum minus* in the Far East and *Streptobacillus moniliformis* in the U.S. and Europe, are sensitive to penicillin G, the drug of choice. Because most cases due to *Streptobacillus* are complicated by bacteremia and, in many instances, by metastatic infections, especially of the synovia and endocardium, high doses given parenterally for 3–4 weeks are frequently recommended.

**Listeria Infections.** Ampicillin or penicillin G (with consideration for addition of gentamicin to both for immunosuppressed patients with meningitis) are the drugs of choice in the management of infections owing to *L. monocytogenes*. The recommended dose of penicillin G is 18–24 million units parenterally for at least 2 weeks. For endocarditis, the dose is the same, but the duration of treatment should be no less than 4 weeks.

**Lyme Disease.** Intravenous penicillin G in doses of 18–24 million units per day for 14 days is an alternative to third-generation cephalosporins in treatment of severe Lyme disease.

**Erysipeloid.** The causative agent of erysipeloid, *Erysipelothrix rhusiopathiae*, is sensitive to penicillin. The infection responds well to a single injection of 1.2 million units of penicillin G benzathine. When endocarditis is present, penicillin G, 12–20 million units per day, for 4–6 weeks is required.

**Pasteurella multocida.** Pasteurella multocida is a cause of wound infections after a cat or dog bite. It is susceptible to penicillin G and ampicillin and resistant to penicillinase-resistant penicillins and first-generation cephalosporins. When the infection causes meningitis, a third-generation cephalosporin is preferred.

**Prophylactic Uses of the Penicillins**

**Streptococcal Infections.** The administration of penicillin to household contacts exposed to *S. pyogenes* pharyngitis has not been shown to be highly effective in reducing subsequent illness. Indications for this type of prophylaxis might include outbreaks of streptococcal disease in closed populations (e.g., boarding schools or military bases).

**Recurrences of Rheumatic Fever.** The oral administration of 200,000 units of penicillin G or penicillin V every 12 h decreases the incidence of recurrences of rheumatic fever in susceptible individuals. The intramuscular injection of 1.2 million units of penicillin G benzathine once a month also yields excellent results. Prophylaxis must be continued throughout the year. Some suggest that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades, but the necessity of lifetime prophylaxis has not been established.

**Syphilis.** Prophylaxis for recent sexual contacts of a patient with primary, secondary, or early latent syphilis consists of a course of penicillin as described for primary syphilis.

### The Penicillinase-Resistant Penicillins

The penicillinase-resistant penicillins are resistant to hydrolysis by staphylococcal penicillinase. Their appropriate use should be restricted to the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme since these drugs are much less active than penicillin G against other penicillin-sensitive microorganisms. However, an increasing number of isolates of *S. aureus* (around half in most U.S. hospitals) and *S. epidermidis* (more than three-quarters) express a low-affinity PBP, giving them the MRSA or MRSE phenotype. This term denotes resistance of these bacteria to all penicillinase-resistant penicillins and cephalosporins (with the exception of ceftaroline and cefobiprole [not available in the U.S.]). Alternative agents such as vancomycin, daptomycin, clindamycin, or linezolid (see Chapter 59) are typically used for infections due to organisms with this resistance mechanism.

**The Isoxazolyl Penicillins: Oxacillin, Cloxacillin, and Dicloxacillin.**

Oxacillin, cloxacillin (not available in the U.S.), and dicloxacillin are semisynthetic penicillin congeners that are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme since these drugs are much less active than penicillin G against other penicillin-sensitive microorganisms. However, an increasing number of isolates of *S. aureus* (around half in most U.S. hospitals) and *S. epidermidis* (more than three-quarters) express a low-affinity PBP, giving them the MRSA or MRSE phenotype. This term denotes resistance of these bacteria to all penicillinase-resistant penicillins and cephalosporins (with the exception of ceftaroline and cefobiprole [not available in the U.S.]). Alternative agents such as vancomycin, daptomycin, clindamycin, or linezolid (see Chapter 59) are typically used for infections due to organisms with this resistance mechanism.

**Pharmacological Properties.** The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci. Dicloxacillin is the most active, and many strains of *S. aureus* are inhibited by concentrations of 0.05–0.8 μg/mL. These agents are, in general, less effective against microorganisms susceptible to penicillin G, and they are not useful against gram-negative bacteria. These agents are absorbed rapidly but incompletely (30%–80%) from the GI tract. Absorption increases when administered 1 h before or 2 h after meals. Peak concentrations in plasma are attained by 1 h. All these congeners are bound to plasma albumin to a great extent (~90%–95%); none is removed from the circulation to a significant degree by hemodialysis. The isoxazolyl penicillins are excreted by the kidney; there is also significant hepatic degradation and elimination in the bile. The half-lives for all are between 30 and 60 min. No dosing adjustments are needed for patients with renal failure.
Nafcillin
This semisynthetic penicillin is highly resistant to penicillinase and has proven effective against infections caused by penicillinase-producing strains of *S. aureus*.

**Pharmacological Properties.** Nafcillin is slightly more active than oxacillin against penicillin G–resistant *S. aureus* (most strains are inhibited by 0.06–2 μg/mL). Although it is the most active of the penicillinase-resistant penicillins against other microorganisms, it is not as potent as penicillin G. The peak plasma concentration is about 8 μg/mL 60 min after a 1-g intramuscular dose. Nafcillin is about 90% bound to plasma protein. Peak concentrations of nafcillin in bile are well above those found in plasma. Dosage adjustment in patients with renal dysfunction is not required. Concentrations of the drug in CSF appear to be adequate for therapy of staphylococcal meningitis.

The Aminopenicillins: Ampicillin and Amoxicillin
Aminopenicillins expand the spectrum of activity of penicillin G in a different direction from the penicillinase-resistant penicillins—they allow for useful activity against some gram-negative organisms. They all are destroyed by β-lactamases (from both gram-positive and gram-negative bacteria); thus, further expansion of their activity is enabled through coformulation with β-lactamase inhibitors (see the end of the chapter for further discussion of the chemistry and activity of β-lactamase inhibitors).

**Antimicrobial Activity**
Ampicillin and amoxicillin are generally bactericidal for sensitive gram-positive and gram-negative bacteria. The meningococci and *L. monocytogenes* are sensitive to this class of drugs. Many pneumococcal isolates have varying levels of resistance to ampicillin, and penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. *Haemophilus influenzae* and the viridans group of streptococci exhibit varying degrees of resistance. Enterococci are about twice as sensitive to ampicillin as they are to penicillin G. From 30% to 50% of *E. coli*, a significant number of *P. mirabilis*, and practically all species of *Klebsiella* are resistant. Most strains of *Shigella*, *Pseudomonas*, *Serratia*, *Acinetobacter*, *B. fragilis*, and indole-positive *Proteus* also are resistant to this group of penicillins. Resistant strains of *Salmonella* are recovered with increasing frequency. Concurrent administration of a β-lactamase inhibitor such as *clavulanate* or *sulbactam* markedly expands their spectrum of activity, particularly against *H. influenzae*, *E. coli*, *Klebsiella*, *Proteus*, and *B. fragilis*.

**ADME**
Ampicillin. Ampicillin is stable in acid and is well absorbed after oral administration. An oral dose of 0.5 g produces peak concentrations in plasma of about 3 μg/mL at 2 h. Intake of food prior to ingestion of ampicillin diminishes absorption. Intramuscular injection of 0.5–1 g sodium ampicillin yields peak plasma concentrations of about 7–10 μg/mL, respectively, at 1 h. Plasma levels decline with a t 1/2 of about 80 min. Severe renal impairment markedly prolongs the t 1/2. Peritoneal dialysis is ineffective in removing the drug from the blood, but hemodialysis removes approximately 40% of the body store in about 7 h. Adjustment of the dose of ampicillin is required in the presence of renal dysfunction. Ampicillin appears in the bile, undergoes enterohpatic circulation, and is excreted in the feces.

Amoxicillin. Amoxicillin, a penicillinase-resistant, semisynthetic penicillin (see Table 57–1), is a close chemical and pharmacological relative of ampicillin. Amoxicillin is stable in acid, designed for oral use, and absorbed more rapidly and completely from the GI tract than ampicillin. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, except that amoxicillin is less active and less effective than ampicillin for shigellosis. Peak plasma concentrations of amoxicillin are 2–2.5 times greater than for ampicillin after oral administration of the same dose. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with amoxicillin is less than that following administration of ampicillin.

The incidence of other adverse effects appears to be similar. Although the t 1/2 of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin because of the more complete absorption. For all these reasons, amoxicillin is generally preferred over ampicillin for oral administration. About 20% of amoxicillin is protein bound in plasma, a value similar to that for ampicillin. Most of a dose of the antibiotic is excreted in an active form in the urine, and dose adjustment is required in renal dysfunction. Probenecid delays excretion of the drug.

**Therapeutic Indications**
Upper Respiratory Infections. Ampicillin and amoxicillin are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*. The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β-lactam antibiotics against both penicillin-susceptible and penicillin-nonsusceptible *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40–45 up to 80–90 mg/kg/d) for empirical treatment of acute otitis media in children is recommended (Lieberthal et al., 2013). Ampicillin-resistant *H. influenzae* is a problem in many areas. The addition of a β-lactamase inhibitor to amoxicillin (clavulanate) or amoxicillin (sulbactam) extends the spectrum to β-lactamase–producing *H. influenzae* and *Moraxella*. Amoxicillin is an alternative treatment to penicillin for bacterial pharyngitis.

Urinary Tract Infections. Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and *E. coli* is the most common species. Aminopenicillins can be effective agents for urinary tract infections, but the high prevalence of resistance amongst *E. coli* and *Klebsiella* makes empiric use of these drugs for urinary tract infections challenging. Enterococcal urinary tract infections are treated effectively with an aminopenicillin alone.

**Meningitis.** Acute bacterial meningitis in children is frequently due to *S. pneumoniae* or *Neisseria meningitidis*. Because 20%–30% of strains of *S. pneumoniae* now may be resistant to ampicillin, it is not indicated for empiric single-agent treatment of meningitis. Ampicillin has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. The combination of ampicillin and vancomycin plus a third-generation cephalosporin is a recommended regimen for empirical treatment of suspected bacterial meningitis in patients at risk for *L. monocytogenes*.

Antipseudomonal Penicillins: The Carboxypenicillins and the Ureidopenicillins

**Antimicrobial Activity**
The carboxypenicillins, carbenicillin and ticarcillin (both discontinued in the U.S.), and the ureidopenicillin, mezlocillin (discontinued in the U.S.) and piperacillin, are active against some isolates of *Pseudomonas aeruginosa* and certain indole-positive *Proteus* spp. that are resistant to ampicillin and its congeners. The carboxypenicillins are ineffective against most strains of *S. aureus*, *Enterococcus faecalis*, *Klebsiella*, and *L. monocytogenes*, but piperacillin (especially when combined with the β-lactamase inhibitor tazobactam) has useful activity against these pathogens and has superior activity against *P. aeruginosa*.

**Pharmacological Properties**
**Carbenicillin Indanyl Sodium.** This indanyl ester of carbenicillin is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to carbenicillin by hydrolysis of the ester linkage. The antimicrobial spectrum of the drug is therefore that of carbenicillin. The active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus, where available, the only use of this drug is for the management of urinary tract infections caused by *Proteus* spp. other than *P. mirabilis* and by *P. aeruginosa*. 

The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β-lactam antibiotics against both penicillin-susceptible and penicillin-nonsusceptible *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40–45 up to 80–90 mg/kg/d) for empirical treatment of acute otitis media in children is recommended (Lieberthal et al., 2013). Ampicillin-resistant *H. influenzae* is a problem in many areas. The addition of a β-lactamase inhibitor to amoxicillin (clavulanate) or amoxicillin (sulbactam) extends the spectrum to β-lactamase–producing *H. influenzae* and *Moraxella*. Amoxicillin is an alternative treatment to penicillin for bacterial pharyngitis.

**Meningitis.** Acute bacterial meningitis in children is frequently due to *S. pneumoniae* or *Neisseria meningitidis*. Because 20%–30% of strains of *S. pneumoniae* now may be resistant to ampicillin, it is not indicated for empiric single-agent treatment of meningitis. Ampicillin has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. The combination of ampicillin and vancomycin plus a third-generation cephalosporin is a recommended regimen for empirical treatment of suspected bacterial meningitis in patients at risk for *L. monocytogenes*.
**CHAPTER 57**

**Penicillins, Cephalosporins, and Other β-Lactam Antibiotics**

### Therapeutic Indications

Piperacillin and related agents are important agents for the treatment of patients with serious infections caused by gram-negative bacteria, including infections often acquired in the hospital. Therefore, these penicillins find their greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to ampicillin; the bacteria especially responsible include *P. aeruginosa*, indole-positive strains of *Proteus*, and *Enterobacter* spp. Because *Pseudomonas* infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β-lactam antibiotic such as piperacillin with good activity against these microorganisms (Freifeld et al., 2012). Because of piperacillin/tazobactam’s good activity against *E. faecalis* and *B. fragilis*, this drug also has utility in mixed intra-abdominal infections.

### Adverse Reactions

**Hypersensitivity Reactions.** Hypersensitivity reactions are by far the most common adverse effects noted with the penicillins, and these agents are amongst the most common causes of drug allergy. Manifestations of hypersensitivity to penicillins include maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens-Johnson syndrome, and anaphylaxis (Romano et al., 2003). Hypersensitivity reactions may occur with any dosage form of penicillin. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (e.g., foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1–2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. In many instances, it is necessary to avoid the future use of penicillin because of the risk of severe reactions, and the patient should be so warned. Patients manifesting hypersensitivity to penicillins may be at increased risk for cross-hypersensitivity reactions on receipt of other β-lactams (cephalosporins, carbapenems). The risk is dependent on the reaction and particular β-lactam administered and is discussed further in the relevant sections for those agents.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety (MDM), which is formed when the β-lactam ring is opened (see Figure 57-4). A large percentage of IgE-mediated reactions are to the MDM, but at least 25% of reactions are to other breakdown products. The terms major and minor determinants refer to the frequency with which antibodies to these haptens appear to be formed. They do not describe the severity of the reaction that may result. In fact, anaphylactic reactions to penicillin usually are mediated by IgE antibodies against the minor determinants. Antipenicillin antibodies are detectable in virtually all patients who have received the drug and in many who have never knowingly been exposed to it. Immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant–specific skin-sensitizing antibodies. Some reactions may be due to toxic antigen-antibody complexes of major-determinant–specific IgM antibodies.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004%–0.04%. About 0.001% of patients treated with these agents die from anaphylaxis. Anaphylaxis most often has followed the injection of penicillin, although it also has been observed after oral or intradermal administration. The most dramatic reaction is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes. Skin rashes of all types may be caused by allergy to penicillin. The incidence of skin rashes appears to be highest following the use of ampicillin, at about 9%. Rashes follow the administration of ampicillin frequently in patients with infectious mononucleosis, but in such cases, patients can tolerate subsequent courses of ampicillin without experiencing a rash (Kerns et al., 1973). Serum sickness of variable intensity and severity, mediated by IgG antibodies, is rare; when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed until 1 or 2 weeks after the drug has been stopped and may persist for a week or longer. Vasculitis may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy, but hemolytic anemia is rare. Reversible neutropenia has been noted, occurring in up to 30% of patients treated with 8–12 g of nafcillin for more than 21 days. The bone marrow shows an arrest of maturation. Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. Penicillins rarely cause interstitial nephritis; methicillin (no longer marketed in the U.S.) has been implicated most frequently. Fever may be the only evidence of a hypersensitivity reaction to the penicillins. The febrile reaction usually disappears within 24–36 h after administration of the drug is stopped but may persist for days.

**Management of the Patient Potentially Allergic to Penicillin.** Evaluation of the patient’s history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Although many patients are labeled as penicillin allergic, studies suggested that 90% or more of patients with a history of penicillin allergy will not manifest immediate hypersensitivity reactions on immunologic testing. Such testing can be performed in the clinical setting through commercially available penicillin skin-testing kits that contain the major antigenic determinant (benzylpenicilloyl polylysine); such testing may, however, fail to detect allergies to minor determinants (Sogn et al., 1992). Occasionally, desensitization is recommended for penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care setting. When full doses are reached, penicillin should not be discontinued and then restarted because immediate reactions may recur. Patients with life-threatening infections (e.g., endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antimicrobial agents should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. Rarely, exfoliative dermatitis with or without vasculitis develops in these patients if therapy with penicillin is continued.

**Other Adverse Reactions.** The penicillins have minimal direct toxicity. Apparent toxic effects include bone marrow depression, granulocytopenia, and hepatitis; the last effect is rare but is seen most commonly following the
administration of oxacillin and nafcillin. The administration of penicillin G and piperacillin (also carbenicillin and ticarcillin) has been associated with impaired hemostasis due to defective platelet aggregation (Fass et al., 1987). Most common amongst the irritative responses to penicillins are pain and sterile inflammatory reactions at the sites of intramuscular injections. In some individuals who receive penicillins intravenously, phlebitis or thrombophlebitis develops. Adverse responses to oral penicillin preparations may include nausea, vomiting, and mild-to-severe diarrhea.

When penicillins are injected accidentally into the sciatic nerve, severe pain occurs and dysfunction in the area of distribution of this nerve develops and persists for weeks. Intrathecal injection of penicillin G may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins should be avoided. Similarly, high CSF concentrations of penicillins achieved through intravenous administration of excessive doses (including failure to adjust for reduced renal clearance) can lead to CNS dysfunction. The rapid intravenous administration of 20 million units of penicillin G potassium, which contains 34 mEq of K⁺, may lead to severe or even fatal hyperkalemia in persons with renal dysfunction. Accidental intravenous instead of intramuscular injection of penicillin G procaine may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of toxic concentrations of procaine. Intravenous injection of benzathine penicillin G has been associated with cardiorespiratory arrest and death.

Reactions Unrelated to Hypersensitivity or Toxicity. Penicillin changes the composition of the microflora in the GI tract by eliminating sensitive microorganisms. Normal microflora are typically reestablished shortly after therapy is stopped; however, in some patients, superinfection results. Pseudomembranous colitis, related to overgrowth and production of a toxin by *Clostridium difficile*, has followed oral and, less commonly, parenteral administration of penicillins.

Mechanism of Action

Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin.

Classification

Classification has been by unofficial generations, based on general features of antimicrobial activity (Table 57-3). Recent development of novel cephalosporins makes further use of this classification scheme problematic, as newer agents expand activity in different ways. In the absence of consensus on a new generations scheme to date, we will continue to employ this scheme for the first three generations and then differentiate agents after the third generation by their notable activity.

The first-generation cephalosporins (e.g., cefazolin, cephalaxin, and cefadroxil) have good activity against gram-positive bacteria and modest activity against gram-negative microorganisms. Most gram-positive cocci (with the exception of enterococci, MRSA, and S. epidermidis) are susceptible. Most oral cavity anaerobes are sensitive, but the B. fragilis group is resistant. These agents have modest activity against Moraxella catarrhalis, E. coli, Klebsiella pneumoniae, and P. mirabilis.

The second-generation cephalosporins have somewhat increased activity against gram-negative microorganisms (including activity against H. influenzae) but are much less active than the third-generation agents.

The third-generation cephalosporins are active against most Enterobacteriaceae, H. influenzae, Moraxella catarrhalis, and Neisseria species. They have good activity against S. aureus, Streptococcus pneumoniae, and S. pyogenes. Activity against Bacteroides spp. is inferior to that of cefoxitin and cefotetan.

Antipseudomonal cephalosporins

Gram-negative activity similar to third generation with addition of activity against Pseudomonas; poor activity vs. gram-positive organisms.

Ceftazidime

Expands ceftazidime's activity against Pseudomonas and multidrug-resistant Enterobacteriaceae, but not against gram-positives.

Ceftriaxone

Similar to ceftazidime, with enhanced activity against Pseudomonas and extended-spectrum \(\beta\)-lactamase-producing Enterobacteriaceae.

Cefepime

Comparable to third generation but more resistant to some \(\beta\)-lactamases (especially those of Pseudomonas and Enterobacteriaceae); gram-positive activity similar to cefotaxime.

Anti-MRSA cephalosporins

Ceftaroline

Similar activity to 3rd generation but with activity against methicillin resistant Staphylococcus aureus.

Ceftriaxone

Not marketed in the U.S.

Cefmetazole

Not marketed in the U.S.

Ceftriaxone

Similar activity to 3rd generation but with activity against methicillin resistant Staphylococcus aureus.

Ceftaroline

Comparable to third generation but more resistant to some \(\beta\)-lactamases (especially those of Pseudomonas and Enterobacteriaceae); gram-positive activity similar to cefotaxime.

Ceftriaxone

Not marketed in the U.S.

Cefmetazole

Not marketed in the U.S.

Ceftriaxone

Similar activity to 3rd generation but with activity against methicillin resistant Staphylococcus aureus.
A subset of second-generation agents (cefoxitin and cefotetan) also has modest activity against *B. fragilis*.

**Third-generation cephalosporins** generally are less active than first-generation agents against gram-positive cocci, although ceftriaxone and cefotaxime in particular have excellent antistreptococcal activity. These agents are much more active than prior generations against the Enterobacteriaceae, although resistance is dramatically increasing due to β-lactamase–producing strains.

**Antipseudomonal cephalosporins** include ceftazidime (sometimes classified as a third-generation cephalosporin) and cefepime. These agents expand on the gram-negative activity of the third generation to provide useful activity against *P. aeruginosa*. Cefazidime and cefotolozane have weaker gram-positive activity than third-generation agents, while cefepime's activity is similar to that of ceftriaxone.

**Anti-MRSA cephalosporins** have structural modifications allowing for binding to and inactivation of the altered PBPs expressed by MRSA, MRSE, and penicillin-resistant *S. pneumoniae*. Cefaroline and cefotib-prole (not available in the U.S.) are the currently used agents in this class. Cefaroline's gram-negative activity is similar to that of ceftriaxone, while cefotib-prole is similar to cefazidime.

None of the cephalosporins has reliable activity against the following bacteria: *Enterococcus; L. monocytogenes; the atypical respiratory pathogens (Legionella pneumophila, Mycoplasma pneumoniae, Chlamydia pneumoniae); Legionella micdadei; C. difficile; Campylobacter jejuni; and Acinetobacter spp.*

### Mechanisms of Bacterial Resistance

As with the penicillins, resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the PBPs that are targets of the cephalosporins. Alterations in two PBPs (1A and 2X) that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three PBPs have inherently low affinity. With the exception of cefaroline and cefotib-prole, cephalosporins lack activity against methicillin-resistant staphylococci due to their inability to bind to the low-affinity PBP expressed by these organisms.

The most prevalent mechanism of resistance to cephalosporins is destruction of the cephalosporins by hydrolysis of the β-lactam ring. The cephalosporins have variable susceptibility to β-lactamases. Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β-lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins (such as ceftazidime and ceftriaxone) are susceptible to hydrolysis by inducible, chromosomally encoded (AmpC) β-lactamases present in gram-negative organisms such as *Citrobacter, Enterobacter,* and *Pseudomonas*. The inductible nature of these β-lactamases leads to a lower degree of susceptibility amongst wild-type isolates, whereas selection for mutants with high-level expression (stable derepression) can lead to clinical resistance. These class C enzymes are not substantially inactivated by classical β-lactamase inhibitors such as clavulanate and tazobactam. Cefepime and cefotibazone, by virtue of their structures, may be less susceptible to hydrolysis by class C β-lactamases than are the third-generation agents. They are, however, susceptible to degradation by KPCs and metallo-β-lactamases. The β-lactamase inhibitor avibactam significantly inhibits the activity of AmpC- and KPC-type β-lactamases and is currently available in a coformulation with ceftazidime.

**General Pharmacology**

Many cephalosporins (cephalexin, cephadine, cefaclor, cefadroxil, loracarbef, cefpizol, cefpodoxime proxetil, cefditoren, and cefditoren) are absorbed readily after oral administration; others can be administered intramuscularly or intravenously. Cephalosporins are excreted primarily by the kidney; thus, in general, the dosage should be reduced in patients with renal insufficiency. Exceptions are cefpiramide (no longer marketed in the U.S.) and cefoperazone, which are excreted predominantly in the bile, and ceftriaxone, which has mixed renal/nonrenal elimination. Just as for penicillins, probenecid slows renal tubular secretion of most cephalosporins. Cefotaxime is deacetylated to a metabolite with less antimicrobial activity than the parent compound that is excreted by the kidneys. The other cephalosporins do not undergo appreciable metabolism. Several cephalosporins, most notably ceftriaxone, cefotaxime, ceftazidime, and cefepime, penetrate into the CSF in sufficient concentration to be useful for the treatment of meningitis. Cephalosporins also cross the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. Concentrations in bile usually are high, especially with cefoperazone and cefpiramide.

**Specific Agents**

### First-Generation Cephalosporins

*Cefazolin* is relatively well tolerated after either intramuscular or intravenous administration; it is excreted by glomerular filtration and is about 85% bound to plasma proteins. Cefazolin is the only parenteral first-generation cephalosporin marketed in the U.S.

*Cephalexin* has the same antibacterial spectrum as the other first-generation cephalosporins. It is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalexin (usually 0.5 g twice to four times daily) results in peak concentrations in plasma adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and 70%–100% is excreted in the urine.

*Cephradine* and *cefaclor* are oral agents similar in activity and pharmacokinetics to cephalexin.

### Second-Generation Cephalosporins

*Cefoxitin* and *cefotetan* are technically cephamycins and are resistant to some β-lactamases produced by gram-negative rods. Typical of second-generation cephalosporins, they have broader gram-negative activity, including most strains of *Haemophilus spp., indole-positive Proteus spp.,* and *Klebsiella spp.* These antibiotics are less active than the first-generation cephalosporins against gram-positive bacteria but are more active against anaerobes, especially *B. fragilis*. *Cefmetazole* is a similar agent only marketed outside the U.S.

*Cefuroxime* has good activity against *H. influenzae* (including strains resistant to ampicillin), *N. meningitidis,* and *S. pneumoniae.* Activity against *E. coli* and *Klebsiella* is modest. Antistaphylococcal activity is inferior to first-generation cephalosporins. Unlike cefoxitin, cefotetan, and cefmetazole, cefuroxime lacks activity against *B. fragilis.* The drug can be given orally, intravenously, or intramuscularly every 8–12 h. Concentrations in CSF are about 10% of those in plasma, and the drug is effective but inferior to ceftriaxone for treatment of meningitis due to susceptible organisms.

*Cefuroxime axetil* is the 1-acetyloxyl ester of cefuroxime. Between 30% and 50% of an oral dose is absorbed, and the drug then is hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

*Cefprozil, cefaclor,* and loracarbef are orally administered agents generally similar to cefuroxime axetil.

### Third-Generation Cephalosporins

*Cefotaxime* is resistant to many narrow-spectrum β-lactamases and has good activity against most gram-positive and gram-negative aerobic bacteria. However, activity against *B. fragilis* is poor, and the increasingly prevalent ESBLs and KPCs confer resistance to cefotaxime. Cefotaxime has a $t_{1/2}$ in plasma of about 1 h and should be administered every 4–8 h for serious infections. The drug is metabolized in vivo to desacetylcefotaxime, which is less active than is the parent compound. Concentrations achieved in the CSF are adequate for treatment of meningitis caused by *H. influenzae,* penicillin-sensitive *S. pneumoniae,* and *N. meningitidis.*

*Ceftriaxone* has activity very similar to that of cefotaxime but a longer $t_{1/2}$ (8 h), allowing for once-daily dosing for most indications. Administration of the drug twice daily has been effective for patients with meningitis. About half the drug can be recovered from the urine; the remainder is eliminated by biliary secretion. Single doses of intramuscular ceftriaxone have long been used in the management of urethral, cervical, rectal, or pharyngeal gonorrhea; increasing resistance has necessitated the use of...
higher doses (250 instead of 125 mg) and routine coadministration of azithromycin (Centers for Disease Control and Prevention, 2015).

Cefitoxime (not marketed in the U.S.) has a spectrum of activity in vitro that is similar to that of cefotaxime, except that it is less active against *S. pneumoniae* and more active against *B. fragilis*. The *t*\(_{\text{1/2}}\) is 1.8 h, and the drug thus can be administered every 8–12 h for serious infections. Cefitoxime is not metabolized; 90% is recovered in urine.

Cefepoxide *proxetil* and cefditoren * pivoxil* are orally administered prodrugs that are hydrolyzed by esterases during absorption to the active forms (cefepoxide and cefditoren, respectively). These drugs provide similar, but less potent, activity as cefotaxime against methicillin-susceptible strains of *S. aureus* and penicillin-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, and *M. catarrhalis*. They are eliminated unchanged in the urine.

Cefixime is orally effective against urinary tract infections caused by *E. coli* and *P. mirabilis*; otitis media caused by *H. influenzae* and *S. pyogenes*; pharyngitis due to *S. pyogenes*; and uncomplicated gonorrhea (although intramuscular ceftriaxone is preferred for gonorrhea). It is available as an oral suspension. Cefixime has a plasma *t*\(_{\text{1/2}}\) of 3–4 h and is both excreted in the urine and eliminated in the bile. The standard dose for adults is 400 mg/day for 5–7 days and for a longer interval in patients with *S. pyogenes*. Doses must be reduced in patients with renal impairment. Pediatric dosing for children 6 months and older and less than 45 kg is based on weight (8 mg/kg/d).

Cefditoren and cefdinir are orally administered cephalosporins similar in spectrum and pharmacokinetics to cefixime.

**Antipseudomonal Cephalosporins**

Cefazidime is one-quarter to one-half as active against gram-positive microorganisms as is cefotaxime; activity against *staphylococci* is particularly poor. Its activity against the Enterobacteriaceae is similar to ceftriaxone, but its major distinguishing feature is excellent activity against *Pseudomonas*. Cefazidime has poor activity against *B. fragilis*.

It only achieves therapeutic levels through parenteral administration, with a *t*\(_{\text{1/2}}\) in plasma of about 1.5 h; the drug is renally eliminated and requires adjustment in renal dysfunction. The activity of cefazidime against ESBL- and KPC-producing Enterobacteriaceae and AmpC *β*-lactamase-overexpressing *Pseudomonas* is enhanced when it is combined with the *β*-lactamase inhibitor avibactam in *ceftazidime/avibactam*.

Ceftolozane is a structural analogue of cefazidime that has enhanced activity against *Pseudomonas*, including activity against strains resistant to cefazidime through *β*-lactamase overexpression. It has similarly weak activity to cefazidime against gram-positive organisms. It is commercially available as the coformulation *ceftolozane/tazobactam*, which improves its activity against ESBL-producing Enterobacteriaceae. Its pharmacokinetics are similar to cefazidime, with a half-life after intravenous administration of approximately 2.5 h and renal elimination.

Cefepime and cefpirome (not available in the U.S.) are parenteral antipseudomonal cephalosporins sometimes also classified as “fourth-generation” agents. They provide similarly excellent activity to cefotaxime against Enterobacteriaceae and are relatively resistant to AmpC chromosomally encoded *β*-lactamases. Thus, they are active against many organisms such as *Enterobacter* and *Pseudomonas* that are resistant to other cephalosporins via overexpression of chromosomally encoded AmpC *β*-lactamases. However, other mechanisms (such as active efflux) in *Pseudomonas* may still confer cefepime resistance. Cefepime is susceptible to varying degrees to hydrolysis by ESBLs and to a great extent to KPCs. Cefepime has higher activity than cefazidime and comparable activity to cefotaxime for streptococci and methicillin-sensitive *S. aureus*.

Cefepime is excreted renally; doses should be adjusted for renal failure. The serum *t*\(_{\text{1/2}}\) is 2 h. Cefepime has excellent penetration into the CSF in animal models of meningitis.

**Anti-MRSA Cephalosporins**

Cefotaroline fosamil is a new cephalosporin with gram-negative activity comparable to cefotaxime. Its distinguishing feature is its enhanced gram-positive activity, especially its ability to bind to the low-affinity PBPs of *MRSA* and penicillin-resistant *S. pneumoniae*. Over 95% of *MRSA* and penicillin-resistant *S. pneumoniae* isolates are inhibited by cefotaroline.

The parenteral preparation is a prodrug that is rapidly converted to active cefotaroline on intravenous administration. It is primarily eliminated by the kidneys with a half-life of approximately 2 h. Cefotaroline has minimal protein binding (~20%) and appears to distribute well into most tissues, though penetration into the CSF has not yet been well characterized.

Ceftibiprole medocaril (not available in the U.S.) has similar activity to cefotaroline against gram-positive organisms. In contrast to all other cephalosporins, it has appreciable in vitro activity against *E. faecalis*; however, its clinical utility against this organism is not established. Its gram-negative spectrum includes activity similar to cefepime against *Pseudomonas* and other gram-negative bacilli. As with cefotaroline, its intravenous formulation is a prodrug that is rapidly cleaved to the active moiety. Its pharmacokinetics are similar to those of cefotaroline.

**Adverse Reactions**

Hypersensitivity reactions to the cephalosporins are the most common side effects; they are similar to those caused by the penicillins. Immediate reactions such as anaphylaxis, bronchospasms, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia. Because of the common *β*-lactam ring structure, there is potential for patients who are allergic to one class of *β*-lactam antibiotics to manifest cross-reactivity to a member of the other class. Some allergic reactions may be directed to the *β*-lactam side chains, which may be similar between agents in different classes. Thus, estimating the likelihood of cross-reactivity between a penicillin and cephalosporin depends on the agents involved; risk seems to be higher with first-generation cephalosporins as opposed to later generations.

Patients with a history of a mild or a temporarily distant reaction to penicillin appear to be at low risk of allergic reaction following the administration of a cephalosporin. However, patients who have a history of a severe, immediate reaction to a penicillin should be skin tested to confirm penicillin allergy before cephalosporin administration, if feasible.

If skin testing is not feasible, administration of a cephalosporin should be avoided if possible. A positive Coombs reaction appears frequently in patients who receive large doses of a cephalosporin, but hemolysis is rare. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia.

Some cephalosporins are potentially nephrotoxic. Renal tubular necrosis has followed the administration of cefaloridine in doses greater than 4 g/d; this agent is not licensed for use in the U.S. Other cephalosporins, when used by themselves in recommended doses, rarely produce significant renal toxicity. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. The high binding affinity of ceftriaxone for serum albumin may displace bilirubin, potentially causing jaundice in neonates; for this reason, cefotaxime is the preferred agent in this patient population. Ceftriaxone's high biliary concentrations combined with its affinity for calcium can lead to biliary pseudolithiasis. Cephalosporins containing a methylthiotetrazole group (ceftamandole [not available in the U.S.], cefotetan, and cefoperazone) can prolong the prothrombin time, an effect that may be associated with clinically significant bleeding amongst patients receiving anticoagulation or with vitamin K deficiency. Encephalopathy and nonconvulsive status epilepticus have been reported with cefepime, especially when administered at high doses or amongst patients with renal dysfunction.

**Therapeutic Uses**

The first-generation cephalosporins are excellent agents for skin and soft tissue infections owing to their activity against *S. pyogenes* and methicillin-susceptible *S. aureus* (Stevens et al., 2014). A single dose of cefazolin just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens (Bratzler et al., 2013).

Second-generation cephalosporins generally have been displaced by third-generation agents. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are...
suboptimal (compared with oral amoxicillin) for treatment of penicillin-nonsusceptible S. pneumoniae pneumonia and otitis media. Cefotixin and cefotetan play a useful role in perioperative prophylaxis for patients undergoing intra-abdominal and gynecologic surgical procedures. They may also be used for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as peritonitis and pelvic inflammatory disease, although because of increasing resistance amongst B. fragilis, these agents are best used for mild-to-moderate infections.

The third-generation cephalosporins are the drugs of choice for serious infections caused by E. coli, Klebsiella, Proteus, Providencia, Serratia, and Hae-
mophilus spp. Ceftriaxone is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. Cefotaxime or ceftaxiran are used for the empiric treatment of meningitis in nonimmunocompromised adults and children (in combination with vancomycin and ampicillin pending identifi-
cation of the causative agent), owing to their excellent activity against H. influ-
enzae, sensitive S. pneumoniae, N. meningitidis, and gram-negative enteric bacteria (Tunkel et al., 2004). Third-generation cephalosporins lack activity against L. monocytogenes and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectra of cefotaxime and ceftaxiran are excellent for the treatment of community-acquired pneumonia.

The antipseudomonal cephalosporins are indicated for the empir-
tical treatment of nosocomial infections where Pseudomonas and other resistant gram-negative bacilli are likely to be pathogens. Cefotolozane/tazo-
bactam may have superior activity against some ceftazidime-resistant Pseudomonas, whereas cefepime has superior activity against nosocomial iso-
lates of Enterobacter, Citrobacter, and Serratia spp. Activity of ceftazidine,
ceftolozane/tazobactam, and cefepime is variable against ESBL-producing isolates and absent against KPC-expressing strains; ceftazidine/avibactam is more likely to be active against these highly resistant organisms.

Other β-Lactam Antibiotics

Carbapenems

Carbapenems are β-lactams that contain a fused β-lactam ring and a five-member ring system that differs from the penicillins because it is unsatu-
rated and contains a carbon atom instead of the sulfur atom. This class of anti-
biotics has a broader spectrum of activity than most other β-lactam antibiotics.

Imipenem

Imipenem is marketed in combination with cilastatin, a drug that inhibits the degradation of imipenem by a renal tubular dipeptidase.

Antimicrobial Activity. Imipenem, like other β-lactam antibiotics, binds to PBPs, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β-lactamases. The activity of imipenem is excellent in vitro for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant S. pneumoniae); enterococci (excluding Enterococcus faecium and non-β-lactamase-producing penicillin-resistant strains); staphylococci (including penicillinase-producing strains but not MRSA); and Listeria (although ampicillin is more active) all are typically suscepti-
ble. Activity is excellent against the Enterobacteriaceae with the exception of emerging KPC-producing strains. Most strains of Pseudomonas and Acinetobacter are inhibited, but resistance to carbapenems amongst these organisms is increasing. Anaerobes, including B. fragilis, are highly suscepti-
able. Imipenem also displays activity against Nocardia spp. and some species of rapidly growing mycobacteria.

Pharmacokinetics and Adverse Reactions. Imipenem is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal tubule. To prolong drug activity, imipenem is com-
bined with cilastatin, an inhibitor of the dehydropeptidase. Both imipenem and cilastatin have a t1/2 of about 1 h. When administered concurrently with cilastatin, about 70% of administered imipenem is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency. Nausea and vomiting are the most common adverse reactions (1%–20%). Seizures have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with renal insufficiency. Patients who are allergic to other β-lactam antibiotics may have hypersensitivity reactions when given imipenem, although the incidence of immediate-type hypersensitivity appears to be low (<1%).

Therapeutic Uses. Imipenem-cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The drug combination appears to be especially useful for the treatment of infections caused by cephalosporin-resistant noso-
comial bacteria. It is prudent to use imipenem for empirical treatment of serious infections in hospitalized patients who have recently received other β-lactam antibiotics. When imipenem is used for treatment of severe P. aeruginosa infections, resistance may develop during therapy.

Meropenem

Meropenem is a derivative of thienamycin. It does not require coadmin-
istration with cilastatin because it is not sensitive to renal dipeptidase. Compared to imipenem, it is somewhat less active against gram-positive organisms (particularly Enterococcus) and more active against gram-
negative organisms. Its toxicity is similar to that of imipenem except that it may be less likely to cause seizures; thus, it is preferred for treatment of meningitis when carbapenem therapy is required.

Doripenem

Doripenem has a spectrum of activity that is similar to that of meropenem, with greater activity against some resistant isolates of Pseudomonas.

Ertapenem

Ertapenem differs from imipenem and meropenem by having a longer t1/2 that allows once-daily dosing and by having inferior activity against Enterococcus, P. aeruginosa, and Acinetobacter spp. Its activity against Enterobacteriaceae and anaerobes makes it useful in intra-abdominal and pelvic infections.

Monobactams

Monobactams are β-lactams that contain only a fused β-lactam ring, not a thiazolidine or dihydrothiazidine ring. Currently, aztreonam is the only member of this class in therapeutic use.

Aztreonam

Aztreonam is resistant to narrow-spectrum β-lactamases elaborated by most gram-negative bacteria as well as metallo-β-lactamases, but not most extended-spectrum or KPC-type β-lactamases. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bac-
teria and anaerobic organisms. Activity against Enterobacteriaceae and P. aeruginosa is similar to that of ceftazidine. It is also highly active in vitro against H. influenzae. Aztreonam is administered either intramuscularly or intravenously. The t1/2 for elimination is 1.7 h; most of the drug is recovered unaltered in the urine. The t1/2 is prolonged to about 6 h in anephric patients. The usual dose of aztreonam for severe infections is 2 g every 6–8 h (reduced in patients with renal insufficiency). A notable feature is a lack of allergic cross-reactivity with other β-lactam antibiotics, with the possible exception of ceftazidine, with which it shares an identical side chain (Perez Pimiento et al., 1998). Aztreonam is therefore useful for treating gram-negative infec-
tions that normally would be treated with a β-lactam antibiotic were it not for a prior allergic reaction. Aztreonam generally is well tolerated, although hepatotoxicity, especially in infants and young children, can occur.

β-Lactamase Inhibitors

Certain molecules can inactivate β-lactamases and prevent the destruction of β-lactam antibiotic substrates. Older-generation β-lactamase inhibitors (clavulananate, sulbactam, tazobactam) are most active against plasmid-encoded β-lactamases (including those that hydrolyze ceftazidine and cefotaxime), but they are inactive at clinically achievable concentrations against the AmpC chromosomal β-lactamases present in gram-negative bacilli (e.g., Enterobacter, Citrobacter, and Pseudomonas) as well as carbapenemases of the KPC- and metallo-β-lactamase type. Avibactam is a new β-lactamase inhibitor that is structurally dissimilar from the older generation, with a broader spectrum of inhibition.
**Clavulanic acid** has poor intrinsic antimicrobial activity but is a "suicide" inhibitor that binds β-lactamases produced by a wide range of gram-positive and gram-negative microorganisms. Clavulanic acid is well absorbed by mouth and also can be given parenterally. It is combined with amoxicillin as an oral preparation and with ticarcillin as a parenteral preparation.

**Sulbactam** is a β-lactamase inhibitor similar in structure to clavulanic acid. It is available for intravenous or intramuscular use combined with ampicillin and with cefoperazone (not available in the U.S.). Sulbactam also possesses intrinsic activity against *Acinetobacter* spp. and has been used in high dosages to treat multidrug-resistant *Acinetobacter* infections.

**Tazobactam** is a β-lactamase inhibitor with good activity against many of the plasmid β-lactamases, including some of the extended-spectrum class. It is available as parenteral combination products with piperacillin and ceftazidime. **Avibactam** is a non-β-lactam β-lactamase inhibitor that provides clinically useful inhibition against narrow-spectrum, ESBL-type, chromosomal AmpC, and KPC-type β-lactamases (although not metallo-β-lactamases). It is available as a parenteral combination product with ceftazidime.

### Bibliography

CHAPTER 57
PENICILLINS, CEPHALOSPORINS, AND OTHER β-LACTAM ANTIBIOTICS

Aminoglycosides contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (Figure 58–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in CSF, and all are excreted relatively rapidly by the normal kidney. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.

**Mechanism of Action**

The aminoglycoside antibiotics are rapidly bactericidal. Bacterial killing is concentration dependent: the higher the concentration, the greater the rate of bacterial killing. The ratio of the peak concentration to the organism's \( \text{MIC} \) is thus a key predictor of aminoglycoside efficacy. The inhibitory activity of aminoglycosides persists after the serum concentration has fallen below the \( \text{MIC} \), a phenomenon known as the postantibiotic effect. These properties probably account for the efficacy of high-dose, extended-interval dosing regimens.

Aminoglycosides diffuse through aqueous channels formed by porin proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on a transmembrane electrical gradient coupled to electron transport to drive permeation of these antibiotics. This energy-dependent phase is rate limiting and can be blocked or inhibited by divalent cations (e.g., \( \text{Ca}^{2+} \) and \( \text{Mg}^{2+} \)), hyperosmolarity, a reduction in pH, and anaerobic conditions. Thus, the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess and in hyperosmolar acidic urine.

Once inside the cell, aminoglycosides bind to polyosomes and interfere with protein synthesis by causing misreading and premature termination...
of mRNA translation (Figure 58–2). The primary intracellular site of 
action of the aminoglycosides is the 30S ribosomal subunit. At least three 
of these ribosomal proteins, and perhaps the 16S ribosomal RNA as well, 
contribute to the streptomycin-binding site. Aminoglycosides interfere with 
the initiation of protein synthesis, leading to the accumulation of abnormal 
initiation complexes; the drugs also can cause misreading of the mRNA 
template and incorporation of incorrect amino acids into the growing 
polypeptide chains (Davis, 1988). The resulting aberrant proteins may be 
inserted into the cell membrane, leading to altered permeability and 
further stimulation of aminoglycoside transport (Busse et al., 1992).

### Antimicrobial Activity

The antibacterial activity of gentamicin, tobramycin, and amikacin 
is directed primarily against aerobic gram-negative bacilli (Mingeot-
Leclercq et al., 1999). Kanamycin, like streptomycin, has a more limited 
spectrum. The aerobic gram-negative bacilli vary in their susceptibility to 
the aminoglycosides (see Table 58–1). Gram-negative aerobic cocci such 
as Neisseria, Moraxella, and Haemophilus have varying susceptibilities. An 
increasing number of gram-negative bacilli encountered in healthcare set-
tings (especially Klebsiella and Pseudomonas) display extensive resistance 
to multiple classes of antibacterials; in these isolates, aminoglycosides may 
be the only class of commonly used agents with in vitro activity.

Aminoglycosides have little activity against anaerobic microorganisms 
or facultative bacteria under anaerobic conditions. Their action against 
most gram-positive bacteria is limited, and they should not be used as 
single agents to treat infections caused by gram-positive bacteria. How-
ever, in combination with a cell wall–active agent, such as a penicillin 
or vancomycin, an aminoglycoside can produce a synergistic bacteri-
cidal effect in vitro. This effect has been most commonly employed for 
treatment of infections due to staphylococci, enterococci, viridans group 
streptococci, and Listeria. Clinically, the superiority of aminoglycoside 
combination regimens over cell-wall agents alone is not proven except in 
relatively few infections (discussed further in the chapter).

### Resistance to the Aminoglycosides

Bacteria may be resistant to aminoglycosides through

- inactivation of the drug by microbial enzymes;
- failure of the antibiotic to penetrate intracellularly; and
- low affinity of the drug for the bacterial ribosome.

---

**Figure 58–1** Aminoglycoside structure and sites of activity of plasmid-mediated enzymes capable of inactivating aminoglycosides. Tobramycin is shown as a representative; structural characteristics protect some aminoglycosides from the actions of some of these enzymes, explaining differences in spectrum of activity.

**Figure 58–2** Effects of aminoglycosides on protein synthesis. A. Aminoglycoside (represented by red circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S-50S ribosomal complex at the start codon (AUG) of mRNA. As 30S-50S complexes downstream complete translation of mRNA and detach, the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to B, premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or C, incorporation of incorrect amino acids (indicated by the red X), resulting in the production of abnormal or nonfunctional proteins.
Clinically, drug inactivation is the most common mechanism for acquired microbial resistance. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids (see Chapter 52). These enzymes phosphorylate, adenylate, or acylate specific hydroxyl or amino groups (see Figure 58–1). The ability of these enzymes to attack these groups in differing aminoglycosides explains some of the variability in antimicrobial activity across the class. Amikacin is a suitable substrate for only a few of these inactivating enzymes; thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to amikacin, particularly amongst gram-negative bacilli. A significant percentage of clinical isolates of Enterococcus faecalis and Enterococcus faecium are highly resistant to all aminoglycosides (Eliaopoulos et al., 1984). Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures between streptomycin and other aminoglycosides, the most common enzyme seen in enterococci does not modify streptomycin, which is inactivated by another enzyme. Consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Transport of aminoglycosides across the cytoplasmic membrane is an active process that depends on oxidative metabolism. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

Missense mutations in Escherichia coli that substitute a single amino acid in a crucial ribosomal protein may prevent binding of streptomycin. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, 5% of strains of Pseudomonas aeruginosa exhibit such ribosomal resistance to streptomycin. Because ribosomal resistance usually is specific for streptomycin, enterococci with ribosomal mutations typically remain sensitive to a combination of penicillin and gentamicin in vitro.

**Absorption**

The aminoglycosides are polar cations and therefore are poorly absorbed from the GI tract. Less than 1% of a dose is absorbed after either oral or rectal administration. Nonetheless, long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of gentamicin from the GI tract may be increased by GI disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into body cavities with serosal surfaces also may result in rapid absorption and unexpected toxicity (i.e., neuromuscular blockade). Intoxication may occur when aminoglycosides are applied topically for long periods to large wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency. All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30–90 min. These concentrations range from 4 to 12 μg/mL following a 1.5- to 2-mg/kg dose of gentamicin, tobramycin, or netilmicin and from 20 to 35 μg/mL following a 7.5-mg/kg dose of amikacin or kanamycin. There is increasing use of aminoglycosides administered via inhalation, primarily for the management of patients with cystic fibrosis who have chronic P. aeruginosa pulmonary infections (Geller et al., 2002). Amikacin and tobramycin solutions for injection have been used, as well as a commercial formulation of tobramycin designed for inhalation.

**Distribution**

Because of their polar nature, the aminoglycosides do not penetrate well into most cells, the CNS, or the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid. The aminoglycosides distribute poorly into adipose tissue, which must be considered when using weight-based dosing regimens in obese patients.

Concentrations of aminoglycosides in secretions and tissues are low (Panidis et al., 2005). High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contributes to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities. Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic (Kearney and Aweeka, 1999). Treatment of meningitis with intravenous administration is generally suboptimal. Intrathecal or intraventricular administration of aminoglycosides has been used to achieve therapeutic levels in the CNS but the availability of extended-spectrum cephalosporins has generally made this unnecessary.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; therefore, these agents should be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.
Metabolism and Excretion

The aminoglycosides undergo minimal metabolism and are excreted almost entirely by glomerular filtration, achieving urine concentrations of 50–200 μg/mL. The half-lives of the aminoglycosides in plasma are 2–3 h in patients with normal renal function. Because the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the t1/2 of all aminoglycosides in patients with moderately compromised renal function. In anephric patients, the t1/2 varies from 20 to 40 times that determined in normal individuals. Because the incidence of nephrotoxicity and ototoxicity is likely related to the overall exposure to aminoglycosides, it is critical to reduce the maintenance dose and dosing interval of these drugs in patients with impaired renal function.

Although excretion of aminoglycosides is similar in adults and children older than 6 months, half-lives of aminoglycosides may be prolonged significantly in the newborn: 8–11 h in the first week of life in newborns weighing less than 2 kg and about 5 h in those weighing more than 2 kg. Thus, it is critically important to monitor plasma concentrations of aminoglycosides during treatment of neonates. Aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis (Mann et al., 1985). Larger doses of aminoglycosides may likewise be required in burn patients because of more rapid drug clearance, possibly because of drug loss through burn tissue. Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis.

Aminoglycosides can be inactivated by various penicillins in vitro and thus should not be admixed in solution (Blair et al., 1982). Some reports indicate that this inactivation may occur in vivo in patients with end-stage renal failure, making monitoring of aminoglycoside plasma concentrations even more necessary in such patients. Amikacin appears to be the aminoglycoside least affected by this interaction; penicillins with more nonrenal elimination (such as piperacillin) may be less prone to cause this interaction.

Dosing and Monitoring

High-dose, extended-interval administration of aminoglycosides is the preferred means of administering aminoglycosides for most indications and patient populations. Administering higher doses at extended intervals (i.e., once daily) is likely to be at least equally efficacious and potentially less toxic than administration of divided doses. This dosing strategy takes advantage of the concentration-dependent activity of aminoglycosides to achieve maximal initial bacterial killing, and because of the postantibiotic effect of aminoglycosides, good therapeutic response can be attained even when concentrations fall below inhibitory concentrations for a substantial fraction of the dosing interval. High-dose, extended-interval dosing schemes for aminoglycosides may also reduce the characteristic ototoxic and nephrotoxicity of these drugs. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. High-dose, extended-interval regimens, despite the higher peak concentration, provide a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (compare the two dosage regimens shown in Figure 58–3).

Populations in which use of the high-dose/extended-interval dosing strategy is more controversial include pregnancy, neonates, and pediatrics and as combination therapy for endocarditis (Contopoulos-Ioannidis et al., 2004; Knoader et al., 2003; Nestas et al., 2005; Ward and Theiler, 2008). In these infections, multiple daily doses (with a lower total daily dose) may be preferred because data documenting equivalent safety and efficacy of extended-interval dosing are limited. Extended-interval dosing is also usually avoided in patients with significant renal dysfunction (i.e., creatinine clearance < 25 mL/min).

Concentrations of aminoglycosides achieved in plasma after a given dose vary widely amongst patients, and therapeutic drug monitoring is standard practice (Bartal et al., 2003). For twice- or thrice-daily dosing regimens, both peak and trough plasma concentrations are determined. The peak concentration documents that the dose produces therapeutic concentrations, while the trough concentration is used to avoid toxicity.

Steady-state trough concentrations should be less than 1–2 μg/mL for gentamicin, netilmicin, and tobramycin and less than 10 μg/mL for amikacin and streptomycin. Peak level goals vary by indication and infection severity, but range from 4 to 8 μg/mL with gentamicin, netilmicin, and tobramycin and 20–35 μg/mL for amikacin. Monitoring of aminoglycoside plasma concentrations also is important when using an extended-interval dosing regimen. For routine monitoring of extended-interval dosing, a single random concentration obtained 6 to 14 h after the start of the infusion can be obtained and plotted against a standard nomogram to determine if dosage adjustment is required (Barclay et al., 1999). However, the most accurate method for monitoring plasma levels for dose adjustment is to measure the concentration in two plasma samples drawn several hours apart (e.g., at 2 and 12 h after a dose). The clearance then can be calculated and the dose adjusted to achieve the desired target range.

Therapeutic Uses of Aminoglycosides

Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for the treatment of most of the infections mentioned in this section. For most indications, gentamicin is preferred because of long experience with its use and its lower cost. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less-toxic agent is contraindicated or less effective.

Aminoglycosides frequently are used in combination with a cell wall–active agent (β-lactam or glycopeptide) for the therapy of serious proven or suspected bacterial infections. The three rationales for this approach are

- to expand the empiric spectrum of activity of the antimicrobial regimen
- to provide synergistic bacterial killing
- to prevent the emergence of resistance to the individual agents
Combination therapy is used in infections such as healthcare-associated pneumonia or sepsis, where multidrug-resistant gram-negative organisms such as *P. aeruginosa*, *Enterobacter*, *Klebsiella*, and *Serratia* may be causative and the consequences of failing to provide initially active therapy are dire. The use of aminoglycosides to achieve synergistic bacterial killing and improve clinical response is most well established for the treatment of endocarditis due to gram-positive organisms, most importantly *Enterococcus* (Le and Bayer, 2003). Clinical data do not support the use of combination therapy for synergistic killing of gram-negative organisms, with the possible exceptions of serious *P. aeruginosa* infections. Aminoglycosides (primarily streptomycin and amikacin) are occasionally used in multidrug regimens for treatment of mycobacterial infections, in part because of the need to suppress the emergence of resistant subpopulations during therapy; data do not strongly support this practice for other bacteria (Bliziotis et al., 2005).

### Urinary Tract Infections

Although the spectrum of activity and concentration in the urinary tract of aminoglycosides make them well-suited for treatment of urinary tract infections, less-toxic alternatives are preferred for uncomplicated infections. However, as strains of *E. coli* have acquired resistance to β-lactams, trimethoprim-sulfamethoxazole, and fluoroquinolones, use of aminoglycosides for urinary tract infections may increase. A single intramuscular dose of gentamicin (5 mg/kg) has been effective in uncomplicated infections of the lower urinary tract. A 10- to 14-day course of gentamicin or tobramycin is an alternative for treatment of pyelonephritis if other agents cannot be used.

### Pneumonia

The organisms that cause community-acquired pneumonia are susceptible to broad-spectrum β-lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Aminoglycosides are ineffective for the treatment of pneumonia due to anaerobes or *Streptococcus pneumoniae*, which are common causes of community-acquired pneumonia. In hospital-acquired pneumonia where aerobic multidrug-resistant gram-negative bacilli are frequently causative pathogens, an aminoglycoside in combination with a β-lactam antibiotic is recommended as standard empiric therapy to increase the likelihood that at least one agent is active against the infecting pathogen (American Thoracic Society, 2005). Once it is established that the β-lactam is active against the causative agent, there is generally no benefit from continuing the aminoglycoside.

### Meningitis

Availability of third-generation cephalosporins, especially cefotaxime and ceftriaxone, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms resistant to β-lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*). If an aminoglycoside is necessary, direct instillation into the CNS is more likely to achieve therapeutic levels than intravenous administration. In adults, this can be achieved with 5 mg of a preservative-free formulation of gentamycin (or equivalent dose of another aminoglycoside) administered intrathecally or intraventricularly once daily.

### Peritonitis

Patients who develop peritonitis as a result of peritoneal dialysis may be treated with aminoglycoside diluted into the dialysis fluid to a concentration of 4–8 mg/L for gentamicin, netilmicin, or tobramycin or 6–12 mg/L for amikacin. Intravenous or intramuscular administration of drug is unnecessary because serum and peritoneal fluid will equilibrate rapidly.

### Bacterial Endocarditis

"Synergistic" or low-dose gentamicin (3 mg/kg/d) in combination with a penicillin or vancomycin has been recommended in certain circumstances for treatment of bacterial endocarditis due to certain gram-positive organisms. Penicillin and gentamicin in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. For this indication, the administration of gentamicin may be given as a consolidated once-daily dose. In cases of enterococcal endocarditis, concomitant administration of penicillin (or ampicillin) and gentamicin (given as divided doses) for 4–6 weeks is recommended as standard therapy. However, safer alternatives such as ampicillin/ceftriaxone combinations or use of the aminoglycoside for only the first 2–3 weeks, are gaining favor to limit the risk of toxicity due to prolonged aminoglycoside administration (Olaison and Schadewitz, 2002). A 2-week regimen of gentamicin in combination with nafcillin is effective for the treatment of selected cases of staphylococcal tricuspid native-valve endocarditis. For patients with native mitral or aortic valve staphylococcal endocarditis, the risks of aminoglycoside administration likely outweigh the benefits (Cosgrove et al., 2009).

### Sepsis

Inclusion of an aminoglycoside in an empirical regimen is commonly recommended for the febrile patient with neutropenia and for sepsis when *P. aeruginosa* is a potential pathogen. However, studies using potent broad-spectrum β-lactams (e.g., carbapenems and antipseudomonal cephalosporins) have demonstrated no benefit from adding an aminoglycoside to the regimen unless there is concern that an infection may be caused by a multiple-drug-resistant organism (Paul et al., 2003). Thus, local susceptibility patterns should be considered when weighing the risks and benefits of adjunctive aminoglycoside administration for empiric therapy in patients with sepsis.

### Tularemia

Streptomycin (or gentamicin) is the drug of choice for the treatment of tularemia. Most cases respond to the administration of 1–2 g (15–25 mg/kg) streptomycin per day (in divided doses) for 10–14 days.

### Plague

A 10-day treatment course of streptomycin or gentamicin is recommended for severe forms of plague (Boulanger et al., 2004).

### Mycobacterial Infections

Streptomycin is a second-line agent for the treatment of active tuberculosis, and streptomycin always should be used in combination with at least one or two other drugs to which the causative strain is susceptible. Amikacin is another alternative agent for infections due to drug-resistant *Mycobacterium tuberculosis* or to other nontuberculous mycobacteria (e.g., *M. avium, M. abscessus, M. chelonae*).

### Cystic Fibrosis

Recurrent infections due to multidrug-resistant gram-negative bacilli, especially *Pseudomonas* species, are a hallmark of cystic fibrosis. Aminoglycosides are frequently used as therapy during acute exacerbations of cystic fibrosis, for which higher-than-standard doses (e.g., 10 mg/kg of tobramycin) are frequently employed due to the usual pharmacokinetics observed in patients with cystic fibrosis. These agents may also be administered via inhalation between exacerbations to improve lung function and reduce exacerbation frequency.

### Topical Applications

Aminoglycosides, especially neomycin and paromomycin, may be employed as topical agents in skin and mucous membrane infections. Oral administration of aminoglycosides may be employed as “bowel prep” prior to surgical procedures or as “selective digestive decontamination” to reduce the risk of ventilator-associated pneumonia.

**Adverse Effects of Aminoglycosides**

All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity and neuromuscular blockade.
Ototoxicity

Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides (Guthrie, 2008). Aminoglycoside-induced ototoxicity may result in irreversible, bilateral, high-frequency hearing loss or vestibular hypofunction. Degeneration of hair cells and neurons in the cochlea correlates with the loss of hearing. Accumulation within the perilymph and endolymph occurs predominantly when aminoglycoside concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are five to six times longer in the otic fluids than in plasma. Drugs such as ethacrynic acid and furosemide potentiate the ototoxic effects of the aminoglycosides in animals, but data from humans implicating furosemide are less convincing (Smith and Lietman, 1983).

Streptomycin and gentamicin produce predominantly vestibular effects, whereas amikacin, kanamycin, and neomycin primarily affect auditory function; tobramycin affects both equally. The incidence of ototoxicity is difficult to determine. Audiometric data suggest that the incidence could be as high as 25% (Brummett and Morrison, 1990). The incidence of vestibular toxicity is particularly high in patients receiving streptomycin; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage. Because the initial symptoms may be reversible, patients receiving high doses or prolonged courses of aminoglycosides should be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued.

A high-pitched tinnitus often is the first symptom of cochlear toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Because perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected except by careful audiometric examination. If the hearing loss progresses, the lower sound ranges are affected.

Amongst patients experiencing vestibular toxicity, moderately intense headache lasting 1–2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1–2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement (“mental past-pointing”), and difficulty in sitting or standing without visual cues. The acute stage ends suddenly and is followed by chronic labyrinthitis, in which the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for about 2 months. Recovery from this phase may require 12–18 months, and most patients have some permanent residual damage. Early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

Nephrotoxicity

Approximately 8%–26% of patients who receive an aminoglycoside for several days develop mild renal impairment that is almost always reversible. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells. The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border followed by mild proteinuria and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days. The nonoliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity of the collecting duct epithelium to vasopressin. Although severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate (Lietman and Smith, 1983). Toxicity correlates with the total amount of drug administered and with longer courses of therapy (de Jager and van Altena, 2002). High-dose, extended-interval dosing approaches lead to less nephrotoxicity at the same level of total drug exposure (as measured by the area under the curve) than divided-dose approaches (see Figure 58–3). Neomycin, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. Streptomycin does not concentrate in the renal cortex and is the least nephrotoxic. Drugs such as amphotericin B, vancomycin, angiotensin-converting enzyme inhibitors, cisplatin, and cyclosporine may potentiate aminoglycoside-induced nephrotoxicity (Wood et al., 1986).

Neuromuscular Blockade

Acute neuromuscular blockade and apnea have been attributed to the aminoglycosides; patients with myasthenia gravis are particularly susceptible. The order of decreasing potency for blockade is neomycin, kanamycin, amikacin, gentamicin, and tobramycin. In humans, neuromuscular blockade generally has occurred after intraperitoneal or intratracheal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even oral administration of these agents. Most episodes have occurred in association with anesthesia or the administration of other neuromuscular blocking agents. Neuromuscular blockade may be reversed by intravenous administration of a Ca2+ salt.

Aminoglycosides may inhibit prejunctional release of acetylcholine while also reducing postsynaptic sensitivity to the transmitter, but Ca2+ can overcome this effect, and the intravenous administration of a calcium salt is the preferred treatment of this toxicity (Sarkar et al., 1992). Inhibitors of acetylcholinesterase (e.g., edrophonium and neostigmine) also have been used with varying degrees of success.

Other Adverse Effects

In general, the aminoglycosides have little allergic potential. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported as cross-hypersensitivity amongst drugs in this class. Aminoglycosides appear to be less commonly associated with superinfection due to Clostridium difficile than other classes of antibacterials.

Pharmacological Properties of Individual Aminoglycosides

Gentamicin

Gentamicin is an important agent for the treatment of many serious gram-negative bacillary infections. It is the aminoglycoside of first choice because of its lower cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin preparations are available for parenteral, ophthalmic, and topical administration. The typical recommended intramuscular or intravenous dose of gentamicin sulfate when used for the treatment of known or suspected gram-negative organisms as a single agent or in combination therapy for adults with normal renal function is 5–7 mg/kg daily given over 30–60 min. For patients with renal dysfunction, the interval may be extended. For patients who are not candidates for extended-interval dosing, a loading dose of 2 mg/kg and then 3–5 mg/kg per day, given as divided doses every 8–12 h, are recommended. Dosages at the upper end of this range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, patients with cystic fibrosis, and others in whom drug clearance is more rapid or volume of distribution is larger than normal.

Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns less than 35 weeks of gestation; 4 mg/kg once daily for newborns more than 35 weeks of gestation; 5 mg/kg daily in two divided doses for neonates with severe infections; and 2–2.5 mg/kg every 8 h for children up to 2 years of age. Peak plasma concentrations range from 4 to 10 mg/mL (dosing: 1.7 mg/kg every 8 h) and 16–24 mg/mL (extended-interval dosing: 5 mg/kg once daily).

It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of
the plasma concentration of aminoglycosides are recommended strongly. Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface, as may be the case in burn patients, plasma concentrations can reach 4 μg/mL, and 2%–5% of the drug may appear in the urine.

**Tobramycin**
The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin are similar to those of gentamicin. Tobramycin may be given intramuscularly, intravenously, or by inhalation. Tobramycin also is available in ophthalmic ointments and solutions. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections known or suspected to be caused by this organism, typically in combination with an antipseudomonal β-lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against many strains of enterococci. Most strains of *E. faecium* are highly resistant. Tobramycin is ineffective against mycobacteria. Dosages and serum concentrations are identical to those for gentamicin.

**Amikacin**
The spectrum of antimicrobial activity of amikacin is the broadest of the group. Because of its resistance to many of the aminoglycoside-inactivating enzymes, amikacin has a special role for the initial treatment of severe nosocomial gram-negative bacillary infections in hospitals where resistance to gentamicin and tobramycin has become a significant problem. Amikacin is active against most strains of *Serratia*, *Proteus*, and *P. aeruginosa* as well as most strains of *Klebsiella*, *Enterobacter*, and *E. coli* that are resistant to gentamicin and tobramycin. Most resistance to amikacin is found amongst strains of *Acinetobacter*, *Providence*, and *Flavobacterium* and strains of *Pseudomonas* other than *P. aeruginosa*; these all are unusual pathogens. Amikacin is less active than gentamicin against enterococci and should not be used for this organism. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against *M. tuberculosis*, including streptomycin-resistant strains and atypical mycobacteria.

The recommended dose of amikacin is 15 mg/kg/d as a single daily dose or divided into two or three equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection, and peak concentrations in plasma approximate 20 μg/mL after injection of 7.5 mg/kg. The concentration 12 h after a 7.5-mg/kg dose is 5–10 μg/mL. A 15-mg/kg once-daily dose produces peak concentrations of 50–60 μg/mL and a trough of less than 1 μg/mL. For treatment of mycobacterial infections, thrice-weekly dosing schedules are used, with doses up to 25 mg/kg (Peloquin et al., 2004). As with the other aminoglycosides, amikacin causes ototoxicity, hearing loss, and nephrotoxicity.

**Netilmicin**
Netilmicin (not marketed in the U.S.) is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage (Panwalker et al., 1978). Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by most of the aminoglycoside-inactivating enzymes; thus, it may be active against certain bacteria that are resistant to gentamicin (with the exception of resistant enterococci). Netilmicin is useful for the treatment of serious infections owing to susceptible Enterobacteriaceae and other aerobic gram-negative bacilli. The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5–2 mg/kg every 12 h. For other serious systemic infections, a total daily dose of 4–7 mg/kg is administered as a single dose or two to three divided doses. Children should receive 3–7 mg/kg/d in two to three divided doses; neonates receive 3.5–5 mg/kg/d as a single daily dose. The *t*½ for elimination is usually 2–2.5 h in adults and increases with renal insufficiency. Netilmicin may produce ototoxicity and nephrotoxicity.

**Streptomycin**
Streptomycin is used for the treatment of certain unusual infections, generally in combination with other antimicrobial agents. It generally is less active than other members of the class against aerobic gram-negative rods. The combination of penicillin G (bacteriostatic against enterococci) and streptomycin is effective as bactericidal therapy for enterococcal endocarditis, although gentamicin is generally preferred for its lesser toxicity. Streptomycin should be used instead of gentamicin when the strain is resistant to the latter and has demonstrable susceptibility to streptomycin, which may occur because the enzymes that inactivate these two aminoglycosides are different.

Streptomycin may be administered by deep intramuscular injection or intravenously. Intramuscular injection may be painful, with a hot tender mass developing at the site of injection. The dose range of streptomycin for most indications is 15–25 mg/kg daily or in divided doses twice daily. During initial therapy for tuberculosis, it is frequently administered as a 1000-mg single daily dose, resulting in peak serum concentrations of about 50–60 and 15–30 μg/mL, and trough concentrations of less than 1 and 5–10 μg/mL, respectively. The dosing frequency may be reduced to two or three times a week after the initial phase of tuberculosis treatment.

Streptomycin has been replaced by gentamicin for most indications because the toxicity of gentamicin is primarily renal and reversible, whereas that of streptomycin is vestibular and irreversible. The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot. Amongst the less-common toxic reactions to streptomycin is peripheral neuritis.
Paromomycin

Paromomycin (also known as aminosidine) is an aminoglycoside that is structurally related to neomycin. It has antibacterial activity similar to other aminoglycosides but has particularly notable antiparasitic activity. Parasites that are usually susceptible to paromomycin include Leishmania spp., Entamoeba histolytica, Giardia lamblia, and Cryptosporidium parvum. Internationally, the parenteral form is used as a treatment of infections due to Leishmania spp. (visceral leishmaniasis), although this formulation is not available in the U.S. (Sundar et al., 2007). Like other aminoglycosides, it has poor systemic absorption when administered orally; this characteristic is exploited to achieve high luminal concentrations in the treatment of intestinal parasitic diseases. It is available as oral capsules and indicated for treatment of intestinal amebiasis at a dose of 25–35 mg/kg/d in three divided doses. It is also used for treatment of intestinal cryptosporidiosis and giardiasis, which can be particularly challenging to treat in immunocompromised patients. Orally administered paromomycin is associated with dose-related gastrointestinal toxicity, including nausea, abdominal pain, and diarrhea. A topical formulation is also used internationally for treatment of cutaneous leishmaniasis (Ben Salah et al., 2013).

Kanamycin

Kanamycin is amongst the most toxic aminoglycosides, and there are few indications for its use. Its primary remaining indication is for treatment of extensively drug-resistant tuberculosis; even in this condition, less-toxic alternatives are generally preferred.

Acknowledgment: Henry F. Chambers contributed to this chapter in recent editions of this book. We have retained some of his text in the current edition.

Bibliography

The agents discussed in this chapter are grouped by their antibacterial mechanism as

1. **bacteriostatic protein synthesis inhibitors that target the ribosome**, such as tetracyclines, macrolides, lincosamides, streptogramins (quinupristin/dalfopristin), and oxazolidinones (e.g., linezolid);
2. **bactericidal agents acting on the cell wall or cell membrane**, such as polymyxins, glycopeptides (e.g., vancomycin), and lipopeptides (daptomycin); and
3. **miscellaneous agents** acting by diverse mechanisms, such as metronidazole, bacitracin, and mupirocin.

### Protein Synthesis Inhibitors That Target the Ribosome

**Tetracyclines and Glycylcyclines**

The tetracyclines are a series of derivatives of a basic four-ring structure shown next for doxycycline. **Demeclocycline**, **tetracycline**, **minocycline**, and **doxycycline** are available in the U.S. for systemic use. Glycylcyclines are tetracycline congeners with substituents that confer broad-spectrum activity and activity against tetracycline-resistant bacteria; the currently available glycylcycline is tigecycline.

**Mechanism of Action**

Tetracyclines and glycylcyclines inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 59–1). These drugs enter gram-negative bacteria by passive diffusion through channels formed by porins in the outer cell membrane and by active transport that pumps tetracyclines across the cytoplasmic membrane.

**Antimicrobial Activity**

Tetracyclines are bacteriostatic antibiotics with activity against a wide range of bacteria. Tetracyclines intrinsically are more active against gram-positive than gram-negative microorganisms. Recent data from the U.S. on the activity of tetracycline and other agents are displayed in Table 59–1. Activity against *Streptococcus pyogenes* and penicillin-susceptible *Streptococcus pneumoniae* is good, but resistance is common in group B streptococci and penicillin-resistant *S. pneumoniae*. Excellent activity is maintained against both MSSA and MRSA. Activity against enterococci is limited. Doxycycline and minocycline can be active against some tetracycline-resistant isolates. *Bacillus anthracis* and *Listeria monocytogenes* are susceptible.

Activity of tetracyclines against *Haemophilus influenzae* has been largely retained since their introduction, but many Enterobacteriaceae have acquired resistance. Although all strains of *Pseudomonas aeruginosa* are resistant, 90% of strains of *Burkholderia pseudomallei* (the cause of melioidosis) are sensitive. Most strains of *Brucella* also are susceptible. Tetracyclines remain useful for infections caused by *Haemophilus ducreyi* (chancroid), *Vibrio cholerae*, and *Vibrio vulnificus* and inhibit the growth of *Campylobacter jejuni*, *Helicobacter pylori*, *Yersinia pestis*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Pasteurella multocida*. Tetracyclines are alternative agents for treatment of actinomycosis.

Tetracyclines are effective against some microorganisms that are resistant to cell-wall-active antimicrobial agents, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia spp.*, *Legionella spp.*, *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenue*.

Glycylcyclines (only tigecycline is currently available) are generally active against organisms that are susceptible to tetracyclines as well as those with acquired resistance to tetracyclines (Gales et al., 2008). In particular, tigecycline displays much greater activity against enterococci, *Enterobacteriaceae*, *Acinetobacter*, and *Bacteroides fragilis*. In surveillance studies, greater than 95% of isolates of these organisms tested susceptible to tigecycline. However, tigecycline still lacks activity against *Pseudomonas*, *Proteus*, and *Providencia* spp. There are a few exceptions where other tetracyclines may be more active than tigecycline against certain organisms, such as *Stenotrophomonas* and *Ureaplasma*.

**Resistance to Tetracyclines and Glycylcyclines**

Resistance is primarily plasmid mediated and often inducible. The three primary resistance mechanisms are as follows:

- Decreased accumulation of tetracycline as a result of either decreased antibiotic influx or acquisition of an energy-dependent efflux pathway
- Production of a ribosomal protection protein that displaces tetracycline from its target
- Enzymatic inactivation of tetracyclines
Cross-resistance, or lack thereof, among tetracyclines depends on which mechanism is operative. Tetracycline resistance due to a ribosomal protection mechanism (tetM) produces cross-resistance to doxycycline and minocycline because the target site protected is the same for all tetracyclines. The glycylamido moiety characteristic of tigecycline reduces its affinity for most efflux pumps, restoring activity against many organisms displaying tetracycline resistance due to this mechanism. Binding of glycyclines to ribosomes is also enhanced, improving activity against organisms that harbor ribosomal protection proteins that confer resistance to other tetracyclines.

**ADME**

Oral absorption of most tetracyclines is incomplete. The percentage of unabsorbed drug rises as the dose increases. Tigecycline is available only for parenteral administration. Concurrent ingestion of divalent and trivalent cations (e.g., Ca++, Mg++, Al3+, Fe++, and Zn++) impairs absorption. Thus, dairy products, antacids, aluminum hydroxide gels; calcium, magnesium, and iron or zinc salts; bismuth subsalicylate and dietary iron and zinc supplements can interfere with absorption of tetracyclines. After a single oral dose, the peak plasma concentration is attained in 2–4 h. These drugs have half-lives in the range of 6–12 h and frequently

</table>

Entries are percentage of isolates inhibited at established or proposed susceptibility breakpoints. In parentheses are drug concentrations (in μg/mL) required to inhibit growth of 90% of isolates of that organism.

NA, not applicable; NR, not reported.

are administered two to four times daily. Demeclocycline also is incompletely absorbed but can be administered less frequently because its $t_1/2$ of 16 h provides effective plasma concentrations for 24–48 h. Oral doses of doxycycline and minocycline are well absorbed (90%–100%) and have half-lives of 16–18 h; they can be administered at lower doses than tetracycline or demeclocycline. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally. Food, including dairy products, does not interfere with absorption of doxycycline and minocycline.

Tetracyclines distribute widely throughout the body, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow and in bone, dentine, and enamel of unerupted teeth. Tigecycline distributes rapidly and extensively into tissues, with an estimated apparent volume of 7–10 L/kg. Inflammation of the meninges is not required for the passage of tetracyclines into the CSF. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relatively high concentrations are found in breast milk.

Except for doxycycline, most tetracyclines are eliminated primarily by the kidney, although they also are concentrated in the liver, excreted in bile, and partially reabsorbed via enterohepatic recirculation. Comparable amounts of tetracycline (i.e., 20%–60%) are excreted in the urine within 24 h following oral or intravenous administration. Doxycycline is largely excreted unchanged in both the bile and urine, tigecycline is mostly excreted unchanged along with a small amount of glucuronidated metabolites, and minocycline is extensively metabolized by the liver before excretion. Hence, no dose adjustment is needed in patients with renal dysfunction. Specific dosage adjustment recommendations in hepatic disease are available only for tigecycline.

**Therapeutic Uses and Dosage**

The tetracyclines remain useful as first-line therapy for infections caused by rickettsiae, mycoplasmas, and chlamydiae. Doxycycline, the most important member of the tetracyclines, is a drug of choice for many sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections and is also used for treatment of respiratory tract infections and for skin and soft-tissue infections caused by community strains of MRSA, for which minocycline also is effective. The glyccyclines have restored much of the antibacterial activity lost to the tetracyclines due to resistance and can be used for a number of infections due to gram-positive and gram-negative organisms (De Rosa et al., 2015). However, a pooled analysis of tigecycline clinical trials found a small but statistically significant increased risk of death with tigecycline versus comparators (Food and Drug Administration, 2016). Thus, tigecycline should generally be reserved for situations in which alternative treatment is not appropriate.

The oral dose of tetracycline ranges from 1 to 2 g/d in adults. Children more than 8 years of age should receive 25–50 mg/kg daily in four divided doses (not to exceed 2 g/d). The typical oral or intravenous dose of doxycycline for adults is 100 mg every 12 or 24 h; for children more than 8 years of age, the dose is 4.4 mg/kg/d in two divided doses the first day, then 2.2 mg/kg given once or twice daily. The typical dose of minocycline for adults is 200 mg orally or intravenously initially, followed by 100 mg every 12 h; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 h. Different dosing recommendations exist for certain diseases (i.e., syphilis); the reader is advised to consult the most current guidelines. Tigecycline is administered intravenously to adults as a 100-mg maintenance dose of 25 mg orally twice a day. Dosage data are not available for tigecycline in pediatrics.

**Respiratory Tract Infections.** Doxycycline has good activity against Streptococcus pneumoniae and H. influenzae and excellent activity against atypical pathogens such as Mycoplasma and Chlamydiophila pneumoniae. Tigecycline is effective for use as a single agent for adults hospitalized with community-acquired bacterial pneumonia.

**Skin and Soft-Tissue Infections.** Tigecycline is approved for the treatment of complicated skin and soft-tissue infections. Doxycycline and minocycline have good activity against staphylococci and may be useful in treatment of cutaneous MRSA infections. Low doses of tetracycline have been used to treat acne (25 mg orally twice a day).

**Intra-abdominal Infections.** Resistance among Enterobacteriaceae and gram-negative anaerobes limits the utility of the tetracyclines for intra-abdominal infections. However, tigecycline possesses excellent activity against these pathogens as well as Enterococcus.

**Sexually Transmitted Diseases.** Doxycycline no longer is recommended for gonococcal infections because of the spread of resistance (Centers for Disease Control and Prevention, 2015). A 7-day treatment course of doxycycline is as effective as, but less convenient than, single-dose azithromycin in the treatment of uncomplicated genital infections due to Chlamydia trachomatis. Chlamydia trachomatis is often a coexistent pathogen in acute pelvic inflammatory disease, and doxycycline is a component of combination therapy regimens for this condition. Acute epididymitis is caused by infection with C. trachomatis or Neisseria gonorrhoeae in men less than 35 years of age. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline for 10 days. Sexual partners also should be treated. Doxycycline for 21 days is first-line therapy for treatment of lymphogranuloma venereum. Nonpregnant penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen, such as doxycycline for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

**Rickettsial Infections.** Tetracyclines are lifesaving in rickettsial infections, including Rocky Mountain spotted fever, scrub typhus, and murine typhus. Tetracyclines are effective for treatment of Rocky Mountain spotted fever in adults and in children, including those less than 9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection (Masters et al., 2003).

**Anthrax.** Doxycycline is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for bioterrorism exposures.

**Local Application.** Except for local use in the eye, topical use of the tetracyclines is not recommended, although they are FDA-approved as over-the-counter topical first-aid antibiotics. Sustained-release preparations of minocycline and doxycycline for subgingival administration are used in dentistry.

**Other Infections.** Tetracyclines in combination with rifampin or streptomycin are effective for acute and chronic infections caused by Brucella melitensis, Brucella suis, and Brucella abortus. Although streptomycin is preferable, tetracyclines also are effective in tularemia. Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide should be used concurrently. Yaws and relapsing fever respond favorably to the tetracyclines. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (Leptospira spp.), Borrelia spp., including B. recurrentis (relapsing fever) and B. burgdorferi (Lyme disease), respond to tetracyclines. The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including Mycobacterium marinum. Tetracyclines in combination with bismuth and metronidazole can be used for H. pylori infections (Peterson et al., 2000).

**Adverse Effects**

**Gastrointestinal.** All tetracyclines can produce GI irritation, most commonly after oral administration. Epigastric burning and distress, abdominal discomfort, nausea, vomiting, and diarrhea may occur. Tolerability can be improved by administering these drugs with food, but tetracyclines should not be taken with dairy products or antacids. Tetracyclines have been associated with esophagitis and esophageal ulcers; patients should take oral formulations with a full glass of water while standing. Tigecycline administered intravenously has also been associated with nausea and vomiting.
Many of the tetracyclines are incompletely absorbed from the GI tract, and high concentrations in the bowel can markedly alter enteric flora. Sensitive aerobic and anaerobic coliform microorganisms and gram-positive spore-forming bacteria are suppressed markedly during long-term tetracycline regimens. As the fecal coliform count declines, overgrowth of tetracycline-resistant microorganisms occurs, particularly of yeasts (Candida spp.), enterococci, Proteus, and Pseudomonas. Moniliasis, thrush, or Candida-associated esophagitis may arise during therapy with tetracyclines.

Photosensitivity. Demeclocycline, doxycycline, and other tetracyclines and, to a lesser extent, glycycline may produce photosensitivity reactions in treated individuals exposed to sunlight. Onycholysis and pigmentation of the nails may develop with or without accompanying photosensitivity.

Hepatic Toxicity. Hepatic toxicity has developed in patients with renal failure receiving 2 g or more of tetracycline per day parenterally, but this effect also may occur when large quantities are administered orally. Pregnant women are particularly susceptible. Doxycycline is probably not associated with hepatotoxicity.

Renal Toxicity. Tetracyclines may aggravate azotemia in patients with renal disease because of the catalytic effects of the drugs. Doxycycline, minocycline, and tigecycline have fewer renal side effects than other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 25). Fanconi syndrome (characterized by nausea, vomiting, polyuria, polydipsia, proteinuria, acidosis, glycosuria, and aminoaciduria) has been observed in patients ingesting outdated tetracycline, presumably due to toxic effects on the proximal renal tubules.

Effects on Teeth. Children treated with a tetracycline or glycycline may develop permanent brown discoloration of the teeth. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk is highest when a tetracycline is given to infants before the first dentition but may develop if the drug is given between the ages of 2 months and 5 years when these teeth are being calcified. Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children.

Other Toxic and Irritative Effects. Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the period of exposure to the drug is short. Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions. Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura. Tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual therapeutic doses. Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24–48 h after drug cessation. Various skin reactions rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after oral use. Other hypersensitivity reactions are burning of the eyes, chills, atopic or hypertrophic glositis, purpura ani or vulvae, and vaginitis; these reactions can persist for weeks or months after cessation of tetracycline therapy. Cross-sensitization among the various tetracyclines is common.

Drug Interactions. As mentioned, oral coadministration of tetracyclines and divalent and trivalent cations can lead to chelation of the tetracycline, with resultant poor absorption. There is some evidence for drug interactions between doxycycline and hepatic enzyme-inducing agents such as phenytoin and rifampin, but not for minocycline or tigecycline.

Chloramphenicol

Chloramphenicol, an antibiotic produced by Streptomyces venezuelae, was introduced into clinical practice in 1948. Chloramphenicol can cause serious and fatal blood dyscrasias; consequently, the drug is now reserved for treatment of life-threatening infections (e.g., meningitis, rickettsial infections) in patients who cannot take safer alternatives because of resistance or allergies (Wareham et al., 2002).

Mechanism of Action

Chloramphenicol inhibits protein synthesis in bacteria and, to a lesser extent, in eukaryotic cells. The drug readily penetrates bacterial cells, probably by facilitated diffusion. Chloramphenicol acts primarily by binding reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and clindamycin). The drug prevents the binding of the amino acid–containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 59–2).

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S); erythroid cells are particularly sensitive.

Antimicrobial Activity

Chloramphenicol possesses a broad spectrum of antimicrobial activity. Chloramphenicol is bacteriostatic against most species, although it may be bactericidal against H. influenzae, Neisseria meningitidis, and S. pneumoniae. Strains of S. aureus tend to be less susceptible, but some isolates of highly resistant MRSA have been susceptible. Chloramphenicol is active against enterococci, including multidrug-resistant E. faecium. Chloramphenicol is active against Mycoplasma, Chlamydia, and Rickettsia. Enterobacteriaceae are variably sensitive to chloramphenicol, but P. aeruginosa is resistant to even very high concentrations of chloramphenicol. Strains of V. cholerae have remained largely susceptible to chloramphenicol. Prevalent strains of Shigella and Salmonella are resistant to multiple drugs, including chloramphenicol.

Figure 59–2 Inhibition of bacterial protein synthesis by chloramphenicol. Chloramphenicol binds to the 50S ribosomal subunit at the peptidyltransferase site, inhibiting transpeptidation. Chloramphenicol binds near the site of action of clindamycin and the macrolide antibiotics. These agents interfere with the binding of chloramphenicol and thus may interfere with each other’s actions if given concurrently. See Figure 59–1 for additional information.
Resistance to Chloramphenicol

Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomal mutation. Acetylated derivatives of chloramphenicol fail to bind to bacterial ribosomes.

ADME

Chloramphenicol has been available in oral, intravenous, and topical (e.g., ophthalmic) preparations. The oral formulation is no longer available in the U.S., although it can be found in other parts of the world. Chloramphenicol administered in oral capsule form is absorbed rapidly from the GI tract. For parenteral use, chloramphenicol succinate is a prodrug that is hydrolyzed by esterases to chloramphenicol in vivo. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug because as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 h) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF. Chloramphenicol is present in bile, milk, and placental fluid. Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol are excreted in the urine. Patients with impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted. About 50% of chloramphenicol is bound to plasma proteins; such binding is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. Variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

Therapeutic Uses and Dosage

Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and less toxic are available, they should be used instead of chloramphenicol.

Typhoid Fever. Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever because they are less toxic and because strains of Salmonella typhi often are resistant to chloramphenicol. The adult dose of chloramphenicol for typhoid fever is 1 g every 6 h for 4 weeks.

Bacterial Meningitis. Chloramphenicol remains an alternative drug for the treatment of meningitis caused by H. influenzae, N. meningitidis, and S. pneumoniae in patients who have severe allergy to β-lactams and in developing countries. The total daily dose for children should be 50 mg/kg of body weight, divided into four equal doses given intravenously every 6 h.

Rickettsial Diseases. The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in pregnant women, and in children less than 8 years of age who require prolonged or repeated courses of therapy, chloramphenicol is an alternative therapy. Rocky Mountain spotted fever, epidemic, murine, scrub, and recrudescence typhus and Q fever respond well to chloramphenicol. For adults and children with these diseases, a dosage of 50 mg/kg/d divided into 6-h intervals is recommended. For severe or resistant infections, doses up to 100 mg/kg/d may be used for short intervals, but the dose must be reduced to 50 mg/kg/d as soon as possible. Therapy should be continued until the general condition has improved and the patient is afebrile for 24–48 h.

Adverse Effects

Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. These include subunits of cytochrome c oxidase, ubiquinone-cytochrome c reductase, and the proton-translocating ATPase critical for aerobic metabolism. Much of the toxicity observed with this drug can be attributed to these effects.

Hypersensitivity Reactions. Skin rashes may result from hypersensitivity to chloramphenicol. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after institution of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

Hematological Toxicity. Chloramphenicol affects the hematopoietic system in two ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Dose-related, reversible erythroid suppression probably reflects an inhibitory action of chloramphenicol on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Bone marrow suppression occurs regularly when plasma concentrations are 25 μg/mL or greater and is observed with the use of large doses of chloramphenicol, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop without prior dose-related marrow suppression.

Pancytopenia occurs more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than one occasion. Although the incidence of the reaction is low, about 1 in 30,000 courses of therapy or more, the fatality rate is high when bone marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for about 70% of cases of blood dyscrasias due to chloramphenicol; hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The proposed mechanism involves conversion of the nitro group to a toxic intermediate by intestinal bacteria.

Other Toxic and Irritative Effects. Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow the oral administration of chloramphenicol. Blurring of vision and digital paresthesias may rarely occur. Tissues that have a high rate of oxygen consumption (e.g., heart, brain) may be particularly susceptible to chloramphenicol’s effects on mitochondrial enzymes.

Neonates, especially if premature, may develop a serious illness termed gray baby syndrome. This syndrome usually begins 2–9 days after treatment is started. Within the first 24 h, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose green stools occur. Over the next 24 h, neonates turn an ashen-gray color and become flaccid and hypothermic. A similar “gray syndrome” has been reported in adults who were accidentally overdosed with the drug. Death occurs in about 40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae. Two mechanisms apparently are responsible for chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, chloramphenicol concentrations in plasma usually exceed 100 μg/mL and may be as low as 75 μg/mL.

Drug Interactions. Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of drugs that are metabolized by this system. Severe toxicity and death have occurred because of failure to recognize such effects. Concurrent administration of phenobarbital or rifampin, which potently induce CYPs, shortens the t1/2 of the antibiotic and may result in subtherapeutic drug concentrations.

Macrolides and Ketolides

Macrolide antibiotics are widely used agents for treatment of respiratory tract infections caused by the common pathogens of community-acquired pneumonia. Four macrolides are available for clinical use: erythromycin, clarithromycin, azithromycin, and fidaxomicin. Erythromycin is the original agent in the class, discovered in 1952 by McGuire and coworkers in the metabolic products of a strain of Streptomyces erythreus.
Azithromycin and clarithromycin are semisynthetic derivatives of erythromycin that have largely replaced it in clinical use. Fidaxomicin is a nonsystemically absorbed macrolide used only for the treatment of *Clostridium difficile* colitis. Ketolides are semisynthetic derivatives of erythromycin with activity against some macrolide-resistant strains.

Macrolide antibiotics contain a multimembered lactone ring (14-membered rings for erythromycin and clarithromycin and a 15-membered ring for azithromycin) to which are attached one or more deoxy sugars. Clarithromycin differs from erythromycin only by methylation of the hydroxyl group at the 6 position, and azithromycin differs by the addition of a methyl-substituted nitrogen atom into the lactone ring. These structural modifications improve acid stability and tissue penetration and broaden the spectrum of activity.

Ketolides are structurally similar multimembered ring systems but with different substituents. Telithromycin differs from erythromycin in that a 3-keto group replaces the α-L-cladinose of the 14-member macrolide ring, and there is a substituted carbamate at C11-C12. Telithromycin is the only ketolide currently approved in the U.S. These modifications render ketolides less susceptible to methylase-mediated (*erm*) and efflux-mediated (*msr*) mechanisms of resistance. Ketolides therefore are active against many macrolide-resistant gram-positive strains; however, concerns about the safety of telithromycin have limited its use (Brinker et al., 2009).

**Mechanism of Action**

Macrolide and ketolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. Erythromycin appears to inhibit the translocation step such that the nascent peptide chain temporarily residing at the A site fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 59–1 for additional information.

**Antimicrobial Activity**

Erythromycin usually is bacteriostatic but may be bactericidal in high concentrations against susceptible organisms. Erythromycin has reasonably good activity against streptococci (see Table 59–1), but macrolide resistance among *S. pneumoniae* often coexists with penicillin resistance. Staphylococci are not reliably sensitive to erythromycin, and macrolide-resistant strains of *S. aureus* are potentially cross-resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli also are frequently sensitive to erythromycin, including *Clostridium perfringens*, *Corynebacterium diphtheriae*, and *L. monocytogenes*. Erythromycin is inactive against most aerobic enteric gram-negative bacilli. It has modest activity in vitro against *H. influenzae* and *N. meningitidis* and good activity against most strains of *N. gonorrhoeae*. Useful antibacterial activity also is observed against *P. multocida*, *Borrelia spp.*, and *Bordetella pertussis*. Macrolides are usually active against *C. jejuni*. Erythromycin is active against *M. pneumoniae* and *Legionella pneumophila*. Most strains of *C. trachomatis* are inhibited by erythromycin.

Azithromycin has similar activity as erythromycin against sensitive strains of streptococci and staphylococci, while clarithromycin is slightly more potent. Clarithromycin is somewhat less active than erythromycin against *H. influenzae*, whereas azithromycin is the most active macrolide. Clarithromycin and azithromycin have good activity against *Moraxella catarrhalis*, *Chlamydia spp.*, *L. pneumophila*, *B. burgdorferi*, *M. pneumoniae*, and *H. pylori*. Azithromycin and clarithromycin have enhanced activity against MAI, as well as against some protozoa (e.g., *Toxoplasma gondii*, *Cryptosporidium*, and *Plasmodium spp.*). Clarithromycin has good activity against *Mycobacterium leprae*. Telithromycin’s spectrum of activity is similar to those of clarithromycin and azithromycin, but its capacity to withstand many macrolide resistance mechanisms increases its activity against macrolide-resistant *S. pneumoniae* and *S. aureus*.

**Resistance to Macrolides and Ketolides**

Resistance to macrolides usually results from one of four mechanisms (Nakajima, 1999):

- Drug efflux by an active pump mechanism
- Ribosomal protection by inducible or constitutive production of methylase enzymes, which modify the ribosomal target and decrease drug binding
- Macrolide hydrolysis by esterases produced by Enterobacteriaceae
- Chromosomal mutations that alter a 50S ribosomal protein (*in Bacillus subtilis*, *Campylobacter spp.*, mycobacteria, and gram-positive cocci)
Erythromycin base is incompletely absorbed from the upper small intestine. Because it is inactivated by gastric acid, it is administered as enteric-coated tablets or as capsules containing enteric-coated pellets that dissolve in the duodenum; food may delay absorption. Esters of erythromycin base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Protein binding is about 70%–80% for erythromycin base and even higher for the estolate. Erythromycin traverses the placenta, and drug concentrations in fetal plasma are about 5%–20% of those in the maternal circulation. Concentrations in breast milk are 50% of those in serum. Erythromycin is concentrated in the liver and excreted in the bile. The serum \( t_{1/2} \) of erythromycin is about 1.6 h. Although the \( t_{1/2} \) may be prolonged in patients with anuria, dosage reduction is not routinely recommended in patients in renal failure. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but hepatic first-pass metabolism reduces its bioavailability to 50%–55%. Peak concentrations occur about 2 h after drug administration. Clarithromycin may be given with or without food, but the extended-release form should be administered with food to improve bioavailability. Clarithromycin and its active metabolite, 14-hydroxyclarithromycin, achieve high intracellular concentrations throughout the body, including the middle ear. Clarithromycin is metabolized in the liver to several metabolites; the active 14-hydroxy metabolite is the most significant. The elimination \( t_{1/2} \) are 3–7 h for clarithromycin and 5–9 h for 14-hydroxyclarithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics and longer half-lives with higher dosages. The amount of clarithromycin excreted unchanged in the urine ranges from 20% to 40%, depending on the dose administered and the formulation (tablet vs. oral suspension). An additional 10%–15% of a dose is excreted in the urine as 14-hydroxyclarithromycin. Dose adjustment is not recommended unless the creatinine clearance is less than 30 mL/min.

Azithromycin administered orally is absorbed rapidly (although incompletely: bioavailability for the immediate-release formulation is on the order of 30%–40%) and distributes widely throughout the body, except to the brain and CSF. Azithromycin also can be administered intravenously, producing plasma concentrations of 3–4 μg/mL after a 1-h infusion of 500 mg. Azithromycin’s unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The elimination \( t_{1/2} \) of 46–8 h, is prolonged because of extensive tissue sequestration and binding.

Telithromycin is formulated as a 400-mg tablet for oral administration; there is no parenteral form. It is well absorbed with about 60% bioavailability. Peak serum concentrations are achieved within 30 min to 4 h. Telithromycin penetrates well into most tissues and is concentrated in many tissues, in particular in macrophages and white blood cells, where concentrations of 40 μg/mL (500 times the plasma concentration) are maintained even 24 h after dosing. Telithromycin has a \( t_{1/2} \) of 9.8 h and can be given once daily. The drug is cleared primarily by hepatic metabolism, 50% by CYP3A4 and 50% by CYP-independent metabolism. No adjustment of the dose is required for those with hepatic failure or mild-to-moderate renal failure.

### Therapeutic Uses and Dosage

The usual oral dose of erythromycin (erythromycin base) for adults ranges from 1 to 2 g/d, in divided doses, usually given every 6 h. Food should not be taken concurrently, if possible, with erythromycin base or the stearate formulations, but this is not necessary with erythromycin estolate. The oral dose of erythromycin for children is 30–50 mg/kg/d, divided into four portions; this dose may be doubled for severe infections. Intravenous administration is generally reserved for the therapy of severe infections and is now used uncommonly; the usual dose is 0.5–1 g every 6 h.

Clarithromycin usually is given twice daily at a dose of 250 mg for adults with mild-to-moderate infections and 500 mg twice daily for more severe infections. The 500-mg extended-release formulation of clarithromycin is given as 2 tablets once daily. Clarithromycin (500 mg) is also packaged with lansoprazole (30 mg) and amoxicillin (1 g) as a combination regimen that is administered twice daily for 10 or 14 days to eradicate *H. pylori*.

Azithromycin should be given 1 h before or 2 h after meals when administered orally. For outpatient therapy of community-acquired pneumonia, pharyngitis, or sinusitis, a loading dose of 500 mg is given on the first day, and then 250 mg per day is given for days 2 through 5. Treatment or prophylaxis of MAI infection in HIV-infected patients requires higher doses: 500–600 mg daily in combination with one or more other agents for treatment or 1200 mg once weekly for primary prevention. Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated (Centers for Disease Control and Prevention, 2015). The treatment of uncomplicated nongonococcal urethritis presumed to be caused by *C. trachomatis* consists of a single 1-g dose of azithromycin. This dose also is effective for chancroid.

Children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum 500 mg) and 5 mg/kg (maximum 250 mg/d) on days 2 through 5. A single 30 mg/kg dose is approved as an alternative for otitis media.

Telithromycin’s dose in adults is 800 mg orally once daily.

#### Respiratory Tract Infections

Macrolides are suitable drugs for the treatment of a number of respiratory tract infections. Azithromycin and clarithromycin are suitable choices for treatment of mild-to-moderate community-acquired pneumonia among ambulatory patients. In hospitalized patients, a macrolide is commonly added to an antipseudomonal β-lactam for coverage of atypical respiratory pathogens. Because of excellent in vitro activity, superior tissue concentration, the ease of administration as a single daily dose, and better tolerability compared to erythromycin, azithromycin (or a fluoroquinolone) has supplanted erythromycin as the first-line agent for treatment of legionellosis. Macrolides are also appropriate alternative agents for the treatment of acute exacerbations of chronic bronchitis, acute otitis media, acute streptococcal pharyngitis, and acute bacterial sinusitis. Azithromycin or clarithromycin are generally preferred to erythromycin due to their broader spectrum and superior tolerability.

Telithromycin is effective in the treatment of community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute bacterial sinusitis and has a potential advantage where macrolide-resistant strains are common. Due to a number of cases of severe hepatotoxicity, the drug’s FDA approval is limited to community-acquired pneumonia; telithromycin should be used only in circumstances where it provides a substantial advantage over less-toxic therapies.

#### Skin and Soft-Tissue Infections

Macrolides are alternatives for treatment of erysipelas and cellulitis among patients who have a serious allergy to penicillin (Stevens et al., 2014). Erythromycin has been an alternative agent for the treatment of relatively minor skin and soft-tissue infections caused by either penicillin-sensitive or penicillin-resistant *S. aureus*. However, many strains of *S. aureus* are resistant to macrolides.

#### Chlamydial Infections

Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg/d in four divided doses for 14 days). Azithromycin, 1 g/week for 3 weeks, may be effective for lymphogranuloma venereum.

#### Diphtheria

Erythromycin for 7 days is very effective for acute infections or for eradicating the diphtheria carrier state. Other macrolides are not FDA-approved for this indication. Antibiotics do not alter the course of an acute infection with diphtheria or decrease the risk of complications. Antitoxin is indicated in the treatment of acute infection.
Pertussis. Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. Clarithromycin and azithromycin also are effective. If administered early in the course of whooping cough, erythromycin may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with erythromycin therapy because resistance has been reported.

**Helicobacter pylori Infection.** Clarithromycin, 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g, each administered twice daily for 10–14 days, is effective for treatment of peptic ulcer disease caused by *H. pylori*. Mycobacterial Infections. Clarithromycin or azithromycin is recommended as first-line therapy for prophylaxis and treatment of disseminated infection caused by MAI in patients with HIV infection and for treatment of pulmonary disease in patients not infected with HIV (Masur et al., 2014). Clarithromycin (500 mg twice daily) plus ethambutol (15 mg/kg once daily) with or without rifabutin is an effective combination regimen. Clarithromycin also has been used with minocycline for the treatment of *M. leprae* in lepromatous leprosy.

**Prophylactic Uses.** Azithromycin or clarithromycin is recommended for primary prevention of infection due to MAI among patients with HIV infection and less than 50 CD4 cells/mm³. Single-agent therapy should not be used for treatment of active disease or for secondary prevention in patients with HIV. Erythromycin is an effective alternative for the prophylaxis of recurrences of rheumatic fever in individuals who are allergic to penicillin.

**Adverse Effects**

**GI Toxicity.** Oral or intravenous administration of erythromycin frequently is accompanied by moderate-to-severe epigastric distress. Erythromycin stimulates GI motility by acting on motilin receptors (see Chapter 51); indeed, erythromycin is used off label as a prokinetic agent in the intensive care setting and in patients with diabetic gastroparesis. Clarithromycin, azithromycin, and telithromycin also may cause GI distress, but to a lesser degree than erythromycin.

**Cardiac Toxicity.** Erythromycin, clarithromycin, azithromycin, and telithromycin have been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. A large cohort study found a small but statistically significant increase in the risk of sudden cardiac death with azithromycin compared to no antibiotic treatment or to amoxicillin. Risk factors for clinically significant cardiac toxicity include receipt of concomitant antiarrhythmic drugs or other agents that prolong QTc.

**Hepatotoxicity.** Cholestatic hepatitis is associated with long-term treatment with erythromycin. The illness starts after 10–20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Findings usually resolve within a few days after cessation of drug therapy. Hepatotoxicity has also been observed with clarithromycin and azithromycin, although at a lower rate than with erythromycin. Telithromycin may induce severe hepatotoxicity and should only be used if it represents a clear advantage over alternative agents (Brinker et al., 2009).

**Other Toxic and Irritative Effects.** Allergic reactions observed are fever, eosinophilia, and skin eruptions, which disappear shortly after therapy is stopped. Auditory impairment and tinnitus have been observed with macrolides, especially at higher doses. Visual disturbances due to slowed accommodation have been reported following telithromycin. Telithromycin is contraindicated in patients with myasthenia gravis due to exacerbation of neurological symptoms.

**Drug Interactions.** Erythromycin, clarithromycin, and telithromycin strongly inhibit CYP3A4 and cause significant drug interactions (Perit et al., 1992). Erythromycin and clarithromycin potentiate the effects of carbamazepine, corticosteroids, cyclosporine, digoxin, ergot alkaloids, theophylline, triazolam, valproate, and warfarin, probably by interfering with CYP-mediated metabolism of these drugs (see Chapter 6). Telithromycin is both a substrate and a strong inhibitor of CYP3A4. Co-administration of rifampin, a potent inducer of CYP, decreases the serum concentrations of telithromycin by 80%. CYP3A4 inhibitors (e.g., itraconazole) increase peak serum concentrations of telithromycin. Azithromycin is much less likely to be involved in these drug interactions; however, caution is advised when the consequences of interaction are severe.

**Lincosamides**

The class originator lincosycin and its congenor clindamycin are approved in the U.S. Clindamycin has largely replaced lincomycin in clinical practice and is principally used to treat gram-positive aerobic and anaerobic infections, as well as some parasitic infections.

**Mechanism of Action**

Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (see Figures 59–2 and 59–3), and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others.

**Antimicrobial Activity**

Bacterial strains are susceptible to clindamycin at MICs of 0.5 μg/mL or less. Clindamycin generally is similar to erythromycin in its in vitro activity against susceptible strains of *S. pneumoniae*, *S. pyogenes*, and viridans streptococci (see Table 59–1). MSSAs usually are susceptible to clindamycin, but MRSA and coagulase-negative staphylococci are more likely to be resistant. Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially *B. fragilis*, but resistance to clindamycin in *Bacteroides* spp. increasingly is encountered. From 10% to 20% of clostridial species other than *C. perfringens* are resistant. Strains of *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for *Pneumocystis jiroveci* pneumonia and *T. gondii* encephalitis, respectively.

**Resistance to Lincosamides**

Macrolide resistance due to ribosomal methylation also may produce resistance to clindamycin. Because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. However, selection for a subpopulation of constitutive methylase producers may occur among staphylococci and streptococci with a macrolide-inducible phenotype (Lewis and Jorgensen, 2005). Clindamycin is not a substrate for macrolide efflux pumps; thus, strains that are resistant to macrolides by this mechanism are susceptible to clindamycin.

**ADME**

Clindamycin is nearly completely absorbed following oral administration. Peak concentrations of 2–3 μg/mL are attained within 1 h after the ingestion of 150 mg. Food in the stomach does not reduce absorption significantly.

the meninges are inflamed, but concentrations sufficient to treat cerebral toxoplasmosis are achievable. The drug readily crosses the placental barrier. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes and alveolar macrophages and in abscesses.

Clindamycin is inactivated by metabolism to N-demethylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Dosage adjustments may be required in patients with severe hepatic failure. Only about 10% of the clindamycin administered is excreted unaltered in the urine, and small quantities are found in the feces.

Therapeutic Uses and Dosage

The oral dose of clindamycin for adults is 150–300 mg every 6 h; for severe infections, it is 300–600 mg every 6 h. Children should receive 8–12 mg/kg/d of clindamycin palmitate hydrochloride in three or four divided doses or, for severe infections, 13–25 mg/kg/d. Clindamycin phosphate is available for intramuscular or intravenous use. For serious infections, intravenous or intramuscular administration is recommended in dosages of 1200–2700 mg/d, divided into three or four equal doses for adults. Children should receive 15–40 mg/kg/d in three or four divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Skin and Soft-Tissue Infections. Clindamycin is an alternative agent for the treatment of skin and soft-tissue infections, especially in patients with β-lactam allergies (Stevens et al., 2014). It is also useful for oral treatment of skin infections when MRSA and streptococci are potential pathogens. Because clindamycin inhibits toxin production, it is recommended as an adjunctive agent in necrotizing fasciitis or gas gangrene when toxin-producing bacteria (e.g., streptococci, staphylococci, clostridia) are suspected. Topical clindamycin is used for treatment of acne.

Respiratory Tract Infections. Clindamycin is effective for treatment of lung abscess and anaerobic lung and pleural space infections due to susceptible organisms (Levison et al., 1983). It has been used as an alternative agent for treatment of sinusitis, pharyngitis, and otitis media. Clindamycin in combination with primaquine is useful for the treatment of mild- to moderate cases of P. jiroveci pneumonia in patients with HIV.

Other Infections. Owing to its good activity against staphylococci and excellent bone penetration, clindamycin is an alternative agent for treatment of osteomyelitis. Clindamycin in combination with pyrimethamine and leucovorin (folinic acid) is an effective alternative for acute treatment of encephalitis caused by T. gondii in patients with AIDS. Clindamycin plus quinine is an alternative regimen for nonsevere malaria. Clindamycin is also administered vaginally for bacterial vaginosis.

Adverse Effects

GI Effects. The reported incidence of diarrhea associated with the administration of clindamycin ranges from 2% to 20%. In most cases, this is mild to moderate in severity and resolves on drug discontinuation. However, clindamycin carries a relatively high risk of superinfection with C. difficile. This colitis is characterized by watery diarrhea, fever, and elevated peripheral white blood cell counts. This syndrome may be lethal. Discontinuation of the drug, combined with administration of metronidazole or oral vancomycin usually, is curative, but relapses occur. Agents that inhibit peristalsis (e.g., opioids) may prolong and worsen the condition.

Other Toxic and Irritative Effects. Skin rashes occur in about 10% of patients treated with clindamycin and may be more common in patients with HIV infection. Other uncommon reactions include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. Clindamycin may potentiate the effect of concomitant neuromuscular blocking agents.

Streptogramins

Streptogramins are semisynthetic derivatives of naturally occurring agents produced by Streptomyces pristinaspiralis. The only streptogramin in clinical use is a fixed combination of quinupristin (a streptogramin B) with dalfopristin (a streptogramin A) in a 30:70 ratio. Quinupristin and dalfopristin are more soluble derivatives of the congeners pristinamycin IA and IIA and therefore are suitable for intravenous administration.

Mechanism of Action

Quinupristin and dalfopristin are protein synthesis inhibitors that bind the 50S ribosomal subunit. Quinupristin binds at the same site as macrolides and has a similar effect, with inhibition of polypeptide elongation and early termination of protein synthesis. Dalfopristin binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of quinupristin at its target site. Dalfopristin directly interferes with polypeptide chain formation. The net result of the cooperative and synergistic binding of these two molecules to the ribosome is bactericidal activity.

Antimicrobial Activity

Quinupristin/dalfopristin is active against gram-positive cocci and organisms responsible for atypical pneumonia (e.g., M. pneumoniae, Legionella spp., and C. pneumoniae) but is inactive against gram-negative organisms (Table 59–1). The combination is bactericidal against streptococci and many strains of staphylococci but bacteriostatic against Enterococcus faecium.

Resistance to Streptogramins

Resistance to quinupristin/dalfopristin is mediated by genes encoding a ribosomal methylase that prevents binding of drug to its target or genes encoding lactonases that inactivate type B streptogramins. Resistance to dalfopristin is mediated by genes that encode acetyltransferases that inactivate type A streptogramins or staphylococcal genes that encode ATP-binding efflux pumps that pump type A streptogramins out of the cell. These resistance determinants are located on plasmids. Resistance to quinupristin/dalfopristin always is associated with a resistance gene for type A streptogramins. Methylase-encoding genes can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is necessary (e.g., endocarditis).

ADM E

Quinupristin/dalfopristin is administered by intravenous infusion over at least 1 h. The t½ is 0.85 h for quinupristin and 0.7 h for dalfopristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalfopristin. Hepatic metabolism by conjugation is the principal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. Hepatic insufficiency increases the plasma AUC of active component and metabolites by 180% for quinupristin and 50% for dalfopristin.

Therapeutic Uses and Dosage

Quinupristin/dalfopristin is approved in the U.S. for complicated skin and skin-structure infections caused by methicillin-susceptible strains of S. aureus or S. pyogenes. It is also used for treatment of infections caused by vancomycin-resistant strains of E. faecium (dose of 7.5 mg/kg every 8–12 h), and in Europe it also is approved for treatment of nosocomial pneumonia and infections caused by MRSA. Quinupristin/dalfopristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant E. faecium.

Adverse Effects

The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias, more likely to be problematic in patients with hepatic insufficiency, are managed by reducing the infusion frequency.

Drug Interactions. Quinupristin/dalfopristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates with quinupristin/dalfopristin may result in significant toxicity. Caution and monitoring are recommended for drugs in which the toxic therapeutic window is narrow or for drugs that prolong the QTc interval.
**CHAPTER 59**

**Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents**

---

**Oxazolidinones**

Oxazolidinones are a new class of synthetic protein synthesis inhibitors with activity primarily against gram-positive organisms, including multidrug-resistant pathogens. Linezolid is the class originator; a second agent, tedizolid, was FDA approved in 2014.

**Antimicrobial Activity**

Linezolid is active against the vast majority of gram-positive organisms, including streptococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as Corynebacterium spp., Nocardia spp., and L. monocytogenes (see Table 59–1). It has poor activity against most gram-negative aerobic or anaerobic bacteria. It is bacteriostatic against enterococci and staphylococci but may be bactericidal against streptococci. Mycobacterium tuberculosis is moderately susceptible, as are most rapidly growing mycobacteria, but MAI is frequently resistant. The available data to date suggest tedizolid has similar activity to linezolid (Ryh Alt, et al., 2014).

**Mechanism of Action**

Oxazolidinones inhibit protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-Met-tRNA complex that initiates protein synthesis. Because of its unique mechanism of action, these agents are active against strains that are resistant to multiple other agents, including penicillin-resistant strains of S. pneumoniae; methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci.

**Resistance to Oxazolidinones**

Resistance in enterococci and staphylococci is most commonly due to point mutations of the 23S rRNA. Because bacteria have multiple copies of 23S rRNA genes, significant resistance generally requires mutations in two or more copies. Recently, a transferable methyltransferase that confers resistance through ribosomal modification has been described. Linezolid resistance remains relatively low among normally susceptible organisms, although some sites report increasing frequency in enterococci, including cases of nosocomial transfer. Although data are limited, tedizolid may be active against some linezolid-resistant isolates.

**ADME**

Linezolid is well absorbed after oral administration, with a bioavailability of 100%, and may be administered without regard to food. Dosing for oral and intravenous preparations is the same. The t 1/2 is about 4–6 h. Linezolid is 30% protein bound and distributes widely to well-perfused tissues. Linezolid is nonenzymatically oxidized to aminooxyacetic acid and hydroxethyl glycine derivatives. Approximately 80% of a dose of linezolid appears in the urine, 30% as active compound and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. No dose adjustment in renal insufficiency is recommended. Linezolid and its breakdown products are eliminated by dialysis; therefore, the drug should be administered after hemodialysis.

Tedizolid is administered orally and parenterally as a prodrug (tedizolid phosphate) that is rapidly and completely hydrolyzed to tedizolid. Tedizolid is well absorbed after oral administration (bioavailability > 80%). Tedizolid displays greater protein binding (70%–90%) and a longer t 1/2, of about 12 h. There is minimal elimination of unchanged drug in the urine; the drug undergoes sulfation in the liver and is excreted primarily in the feces.

**Therapeutic Uses and Dosage**

Linezolid is most commonly administered at a dose of 600 mg twice daily orally or intravenously. A 400-mg twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections in adults. Tedizolid is given as a 200-mg IV or oral daily dose.

**Skin and Soft-Tissue Infections.** Linezolid and tedizolid are FDA approved for treatment of skin and skin-structure infections caused by streptococci and S. aureus (MSSA and MRSA). A 6-day regimen of tedizolid provided similar outcomes to a 10-day regimen of linezolid (Barnett et al., 2014), provided at a dose of 600 mg twice daily orally for 7 days.

**Respiratory Tract Infections.** Linezolid is approved for treatment of community-acquired pneumonia due to S. pneumoniae and nosocomial pneumonia due to S. aureus. A randomized clinical trial in patients with MRSA pneumonia demonstrated similar or better outcomes to vancomycin (Wunderink et al., 2012). Studies of tedizolid for pneumonia are under way.

**Other Infections.** Linezolid has clinical and microbiological cure rates in the range of 85%–90% in treatment of a variety of infections caused by vancomycin-resistant E. faecium. Linezolid has been used in combination therapy for extensively drug-resistant tuberculosis and in infections due to Nocardia.

**Adverse Effects**

**Myelosuppression.** Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving linezolid. Thrombocytopenia tends to be the most common effect, with an onset between 7 and 10 days. Effects are reversible on drug discontinuation. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function and in patients receiving courses of therapy lasting beyond 2 weeks. Treatment durations with tedizolid in clinical trials have been limited; based on early clinical and in vitro data, tedizolid may have a lower propensity for causing myelosuppression.

**Mitochondrial Toxicities.** Patients receiving treatment with linezolid have developed peripheral neuropathy, optic neuritis, and lactic acidosis (Narita et al., 2007). These effects typically manifest after prolonged treatment durations (at least 6 weeks), although some cases of lactic acidosis have been described after only a few days of therapy. The underlying mechanism of these toxicities is believed to be inhibition of mitochondrial protein synthesis. Linezolid should generally not be used for long-term therapy if there are alternative agents. There are insufficient data to judge the risk of mitochondrial toxicities with tedizolid.

**Drug Interactions.** Linezolid is a weak nonspecific inhibitor of MAO. Patients receiving concomitant therapy with an adrenergic or serotonergic agent (including SSRIs) or consuming more than 100 mg of tyramine a day may experience serotonin syndrome (e.g., palpitations, headache, hypertensive crisis). Coadministration of these agents is best avoided. However, in patients receiving SSRIs who acutely require linezolid therapy for short-term (10- to 14-day) treatment, coadministration with careful monitoring is reasonable. The relative potential for this interaction with tedizolid is not yet known. Neither linezolid nor tedizolid is a substrate or an inhibitor of CYPs.

**Agents Acting on the Bacterial Cell Wall**

**Polymyxins**

The polymyxins are a group of closely related antibiotics elaborated by strains of Bacillus polymyxa. Polymyxin B is a mixture of polymyxins B1 and B2. Colistin, also known as polymyxin E, is produced by Bacillus colistinus and is marketed either as colistimethate for intravenous administration or colistin base for topical use. These agents were initially developed more than 50 years ago but quickly fell out of favor for systemic use due to their toxicities. With the rise of resistant gram-negative organisms in the past decade, their use has increased substantially.

**Antimicrobial Activity**

The antimicrobial activities of polymyxins B and colistin are similar and restricted to gram-negative bacteria, primarily aerobes. Most Pseudomonas, Acinetobacter, and Enterobacteriaceae are susceptible, except for Proteus and Serratia spp. Stenotrophomonas and Burkholderia are usually resistant.

**Mechanism of Action**

Polymyxins, simple basic peptides with molecular masses of about 1000 Da, are surface-active amphipathic agents that act as cationic detergents. They interact strongly with phospholipids and disrupt the structure of the bacterial cell.
cell membranes. Sensitivity to polymyxin B apparently is related to the phospholipid content of the cell wall–membrane complex. Polymyxin B binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule.

**Resistance to Polymyxins**

Although resistance to polymyxins is rare, emergence of resistance while on treatment has been documented and has become problematic among extensively drug-resistant *Acinetobacter* and *Klebsiella*.

**ADME**

Polymyxin B and colistin are not absorbed when given orally and are poorly absorbed from mucous membranes and surfaces of large burns. CMS (colistimethate) is the prodrug formulation for parenteral administration; it is hydrolyzed relatively slowly in the bloodstream to the active colistin sulfate moiety. CMS may be administered via inhalation for prevention and adjunctive treatment of lung infections. Limited data are available regarding distribution of these agents in the body. Intraventricular and intrathecal administration has been used for treatment of CNS infections. CMS (but not colistin) is cleared renally; thus modification of the dose is generally required in patients with impaired renal function. Polymyxin B primarily undergoes nonrenal clearance.

**Therapeutic Uses and Dosage**

Because dosing of these agents varies by drug (polymyxin B or colistin), by the particular commercial preparation marketed in a specific country, and by the patient's degree of renal dysfunction, expert consultation is recommended.

**Systemic Uses.** Polymyxins are used systemically only for serious infections due to pathogens resistant to other effective therapies. They have been used for treatment of a variety of infections, including bacteremia, pneumonia, bone/joint infections, burns, cellulitis, cystic fibrosis, endocarditis, gynecologic infections, meningitis, and ventriculitis (Nation et al., 2015).

**Topical Uses.** Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Infections of the skin, mucous membranes, eye, and ear due to polymyxin B–sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *Pseudomonas aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative.

**Adverse Effects**

The primary toxicity of polymyxins is dose-related nephrotoxicity. Neurological reactions include muscle weakness, apnea, paresthesias, vertigo, and slurred speech. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitivity reactions are uncommon.

---

**Glycopeptides**

The class originator for glycopeptides is vancomycin, a tricyclic glycopeptide antibiotic produced by *Streptococcus orientalis*. Teicoplanin is a mixture of related glycopeptides available as an antibiotic in Europe. It is similar to vancomycin in chemical structure, mechanism of action, spectrum of activity, and route of elimination (i.e., primarily renal). A new generation of glycopeptide congeners, the lipoglycopeptides, has been recently introduced into clinical practice. These agents include telavancin, dalbavancin, and oritavancin (Henson et al., 2015).

**Antimicrobial Activity**

Vancomycin possesses activity against the vast majority of gram-positive bacteria (see Table 59–1), including MRSA, penicillin-resistant streptococci, and ampicillin-resistant enterococci. Gram-positive organisms intrinsically resistant to vancomycin include *Lactobacillus*, *Leuconostoc*, *Pediococcus*, and *Erysipelothrix*. Essentially all species of gram-negative bacilli and mycobacteria are resistant to glycopeptides. The activity of teicoplanin, telavancin, dalbavancin, and oritavancin is generally similar to that of vancomycin; these agents are also active against some vancomycin-resistant enterococci (Goldstein et al., 2004).

**Mechanism of Action**

Glycopeptides inhibit the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the β-alanyl-β-alanine terminus of cell wall precursor units (Figure 59–4). Because of their large molecular size, they are unable to penetrate the outer membrane of gram-negative bacteria. The lipoglycopeptides are able to dimerize and anchor their lipid moieties into the bacterial cell membrane, allowing for increased binding to the β-Ala-β-Ala target site and improved potency. Telavancin and oritavancin possess a second mechanism of action: direct disruption of the bacterial cell membrane. This effect leads to more rapid bactericidal activity than that of vancomycin.

**Resistance to Glycopeptides**

Glycopeptide-resistant strains of enterococci, primarily *E. faecium*, have emerged as major nosocomial pathogens in hospitals in the U.S. Determinants of vancomycin resistance are located on a transposon that is readily transferable among enterococci, and, potentially, other gram-positive bacteria. These strains are typically resistant to multiple antibiotics, including streptomycin, gentamicin, and ampicillin. Resistance to streptomycin and gentamicin is of special concern because the combination of an aminoglycoside with a cell wall synthesis inhibitor is the only reliably bactericidal regimen for treatment of enterococcal endocarditis.

Enterococcal resistance to glycopeptides is the result of alteration of the β-alanyl-β-alanine target to β-alanyl-β-lactate or β-alanyl-β-serine, which bind glycopeptides poorly. Several enzymes within the van gene cluster are required for this target alteration to occur. The vanA genotype confers inducible resistance to teicoplanin and vancomycin in *E. faecium* and *Enterococcus faecalis*. Consistent with their dual mode of action, while MICs to telavancin and oritavancin may increase in isolates expressing vanA,
they often remain in the susceptible range. In contrast, vanA-expressing isolates are frequently dalbavancin resistant. The vanB genotype, which tends to be a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible by vancomycin but not teicoplanin; consequently, many strains remain susceptible to teicoplanin. Telavancin, dalbavancin, and oritavancin are usually active as well. The vanC genotype, the least important clinically and least well characterized, confers resistance only to vancomycin.

*Staphylococcus aureus* and coagulase-negative staphylococci may express reduced or “intermediate” susceptibility to vancomycin (MIC 4–8 μg/mL) or, very rarely, high-level resistance (MIC ≥ 16 μg/mL) (Howden et al., 2004). Intermediate resistance is associated with a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10^6 to 1 in 10^7) will grow in the presence of vancomycin concentrations greater than 4 μg/mL. Prior treatment courses and low vancomycin levels may predispose patients to infection and treatment failure with vancomycin-intermediate strains. These strains typically are resistant to methicillin and multiple other antibiotics; their emergence is a major concern because until recently vancomycin has been the only antibiotic to which staphylococci were reliably susceptible. High-level vancomycin-resistant *S. aureus* strains (MIC ≥ 32 μg/mL) harbor a conjugative plasmid into which the vanA transposon is integrated by an interspecies horizontal gene transfer from *E. faecalis* to an MRSA. These isolates have been variably susceptible to teicoplanin and the lipoglycopeptides (Centers for Disease Control and Prevention, 2004).

**ADME**

All glycopeptides are poorly absorbed after oral administration; the oral formulation of vancomycin is exclusively used in patients with *C. difficile* colitis. Vancomycin should be only administered intravenously, not intramuscularly, due to pain with intramuscular injection. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed (7%–30%); bile; and pleural, pericardial, synovial, and ascitic fluids. About 90% of an injected dose of vancomycin is excreted by glomerular filtration; elimination t½ is about 6 h in normal renal function. The drug accumulates if renal function is impaired, and dosage adjustments must be made. The drug can be cleared from plasma with hemodialysis. Teicoplanin can be administered by intramuscular injection as well as intravenous administration. An intravenous dose of 1 g in adults produces plasma concentrations of 15–30 μg/mL 1 h after a 1- to 2-h infusion. Teicoplanin is highly bound by plasma proteins (90%–95%) and has an extremely long serum elimination t½ (up to 100 h), allowing for once-daily dosing. Excretion is through glomerular filtration.

Telavancin achieves peak concentrations of approximately 90 μg/mL when administered intravenously at a dose of 10 mg/kg once daily. Telavancin is highly protein bound (90%), with a t½ of about 7 h. Studies of penetration into epithelial lining fluid and skin blister fluid demonstrated adequate tissue concentrations to provide effective therapy. Telavancin is eliminated primarily (70%–80%) by renal excretion, with a small component of metabolism. Dosage adjustment is required in renal dysfunction.

Dalbavancin and oritavancin have unique pharmacokinetic properties that allow for intermittent (weekly or less) dosing. Both are characterized by extremely long plasma half-lives (on the order of 10 days for terminal elimination) and are highly (90%) protein bound. Penetration of dalbavancin into skin blister fluid and bone appears to be adequate, but penetration into CSF is very low. Between 33% and 50% of dalbavancin is eliminated unchanged in the urine, and dosage adjustment is recommended for renal dysfunction. Oritavancin has a large volume of distribution (~1 L/kg). Renal excretion is very slow and dosage adjustment is not required in moderate renal dysfunction.

**Therapeutic Uses and Dosage**

Vancomycin hydrochloride is available for intravenous use as a sterile powder for solution. It should be diluted and infused over at least a 60-min period to avoid infusion-related adverse reactions; the recommended initial dose for adults is 30–45 mg/kg/d in two or three divided doses. Current recommendations call for monitoring serum trough concentrations (within 30 min prior to a dose) at steady state, typically before the fourth dose of a given dosage regimen (Rybak et al., 2009). A trough serum concentration of at least 10 μg/mL is recommended. For patients with more serious infections (including endocarditis, osteomyelitis, meningitis, and MRSA pneumonia), trough levels of 15–20 μg/mL are recommended. Pediatric doses are as follows: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 h; for infants 8–30 days old, 15 mg/kg followed by 10 mg/kg every 8 h; for older infants and children, 10–15 mg/kg every 6 h. Alteration of dosage is required for patients with impaired renal function. In functionally anephric patients and patients receiving dialysis with non–high-flux membranes, administration of 1 g (≤15 mg/kg) every 5–7 days typically achieves adequate serum levels. In patients receiving intermittent high-efficiency or high-flux dialysis, maintenance doses administered after each dialysis session are typically required. For treatment of *C. difficile* colitis, vancomycin is available as capsules for oral administration; alternatively, the intravenous formulation may be compounded into a solution for oral administration. The recommended oral dose of vancomycin is 125 mg four times daily, with escalation up to 500 mg four times daily in patients with life-threatening disease.

Telavancin is administered intravenously at a dose of 10 mg/kg daily, with dosage adjustment required for patients with renal dysfunction. The approved dosage of intravenous dalbavancin for treatment of skin and soft-tissue infection is 1000 mg at the initiation of treatment, followed by a 500-mg dose 7 days later. Oritavancin has been studied for skin and soft-tissue infections as a single 1200-mg intravenous dose.

**Skin/Soft-Tissue and Bone/Joint Infections.** Vancomycin has long been a mainstay in the treatment of skin/soft-tissue and bone/joint infections, where gram-positive organisms, including MRSA, are the leading pathogens (Stevens et al., 2014). Telavancin, dalbavancin, and oritavancin offer alternatives for treatment of this condition, with dalbavancin and oritavancin offering the option for infrequent dosing.

**Respiratory Tract Infections.** Vancomycin is employed for the treatment of pneumonia when MRSA is suspected. Because vancomycin penetration into lung tissue is relatively low, aggressive dosing is generally recommended. Telavancin displayed similar efficacy to vancomycin in studies of nosocomial pneumonia due to gram-positive pathogens.

**CNS Infections.** Vancomycin is a key component in the initial empirical treatment of community-acquired bacterial meningitis in locations where penicillin-resistant *S. pneumoniae* is common (Tunkel et al., 2004). Penetration of vancomycin across meninges is poor, especially with steroid coadministration; thus, aggressive dosing is typically warranted. Vancomycin is also used to treat nosocomial meningitis often caused by staphylococci. Intraventricular vancomycin has been used in ventricular shunt infections.

**Endocarditis and Vascular Catheter Infections.** Vancomycin is standard therapy for staphylococcal endocarditis when the isolate is methicillin resistant or patients have a severe penicillin allergy (Baddour et al., 2005). However, β-lactams such as nafcillin or cefazolin are more effective than vancomycin for treatment of MSSA bloodstream infections; thus, patients should only receive vancomycin for MSSA infections if they have a documented, life-threatening allergy. Vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy or for penicillin-resistant isolates. Vancomycin is used for the treatment of vascular catheter infections due to gram-negative organisms.

**Other Infections.** Vancomycin is the drug of choice for patients with moderate-to-severe pseudomembranous colitis due to *C. difficile*. Vancomycin is frequently employed as a component of empiric therapy for patients with fever and neutropenia. It is also used in surgical prophylaxis in patients with β-lactam allergies or if there is a high risk of MRSA infection.

**Adverse Effects**

**Infusion-Related Reactions.** Rapid intravenous infusion of vancomycin may cause erythematous or urticarial reactions, flushing, tachycardia, and
hypotension (“red man” or “red neck” syndrome). The extreme flushing that can occur is not an allergic reaction but a direct effect of vancomycin on mast cells, causing them to release histamine. Typically, this reaction can be ameliorated by administering vancomycin more slowly; sometimes with premedication with histamine blockers. This reaction is generally not observed with teicoplanin but has been reported with lipoglycopeptides (i.e., telavancin).

**Nephrotoxicity.** Initial formulations of vancomycin contained impurities that were associated with a high incidence of nephrotoxicity. With the availability of formulations free of the impurities, there was a question regarding whether vancomycin was intrinsically nephrotoxic. As such, as the recommended dosage range for vancomycin dosages has increased, it seems clear there is indeed a degree of dose-related nephrotoxicity (Lodise et al., 2009). Results of clinical trials suggest telavancin's nephrotoxicity may exceed that of vancomycin.

**Other Toxic and Irritative Effects.** True hypersensitivity reactions produced by glycopeptides are less common than the pseudoallergic infusion-related reactions and include macular skin rashes and anaphylaxis. Because of the long half-lives of dalbavancin and oritavancin, there is concern over prolonged effects if patients were to experience a severe hypersensitivity reaction. Telavancin can cause QT interval prolongation and is contraindicated in pregnancy due to teratogenic effects observed in animal studies. Auditory impairment, sometimes permanent, has been described in association with vancomycin use; some investigators believe ototoxicity is associated with excessive concentrations of vancomycin in plasma (60–100 μg/mL or greater).

**Drug Interactions.** Oritavancin has a minor effect on CYP-mediated metabolism; it should be used with warfarin only with careful monitoring. Caution should be used when using other nephrotoxic drugs with vancomycin or telavancin due to risks for additive nephrotoxicity.

**Lipopeptides**

Daptomycin, the only member of its class, is a cyclic lipopeptide antibiotic derived from Streptomyces roseosporus with bactericidal activity against gram-positive bacteria, including vancomycin-resistant isolates (Carpenter et al., 2004).

**Antimicrobial Activity**

Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria (see Table 59–1). Daptomycin may be active against vancomycin-resistant strains, although MICs tend to be higher for these organisms than for their vancomycin-susceptible counterparts (Critchley et al., 2003).

**Mechanism of Action**

Daptomycin binds to bacterial membranes, resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity.

**Resistance to Lipopeptides**

Daptomycin resistance has been reported to emerge while on therapy. Resistance occurs most commonly in treatment of high-inoculum infections (such as endocarditis) and among enterococci. The mechanisms of resistance to daptomycin have not been fully characterized but appear to be related to changes in cell surface charge that impede daptomycin binding. Interestingly, coadministration of β-lactams with daptomycin (even when the pathogen is resistant to the β-lactam) can reverse this resistance, suggesting potential combination therapy regimens.

**ADME**

Daptomycin is poorly absorbed orally and should be administered only intravenously. Direct toxicity to muscle precludes intramuscular injection. The serum t1/2 is 8–9 h, permitting once-daily dosing. Approximately 80% of the administered dose is recovered in urine; a small amount is excreted in feces. Although the drug penetrates adequately into the lung, the drug is inactivated by pulmonary surfactant and thus is not useful in the treatment of pneumonia (Silverman et al., 2005). If the creatinine clearance is less than 30 mL/min, the dose is administered only every 48 h. For patients on hemodialysis, the dose should be given immediately after dialysis.

**Therapeutic Uses and Dosage**

Daptomycin is indicated for treatment of complicated skin and soft-tissue infections (at 4 mg/kg/d) and complicated bacteremia and right-sided endocarditis (at 6 mg/kg/d), where its efficacy is comparable to that of vancomycin or antistaphylococcal β-lactams (Fowler et al., 2006). Use of higher doses (8–10 mg/kg) appears to be well tolerated and may provide additional benefit in difficult-to-treat infections (Figueroa et al., 2009).

**Adverse Effects**

**Musculoskeletal Toxicity.** Elevations of creatine kinase may occur; this does not require discontinuation unless findings suggest an otherwise-unexplained myopathy. Rhabdomyolysis has been reported to occur rarely.

**Drug Interactions.** Daptomycin does not affect CYPs and has no important drug-drug interactions. Caution is recommended when daptomycin is coadministered with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively.

**Miscellaneous Agents**

**Metronidazole**

Metronidazole is a nitroimidazole with broad activity against parasites and anaerobic bacteria. Only its antibacterial activity is discussed next; for an in-depth description, see Chapter 54.

**Antimicrobial Activity and Resistance**

The nitro group of metronidazole is reduced in anaerobic bacteria and some protozoans, producing the active form of the drug that interacts with DNA, disrupting its structure and inhibiting replication. Metronidazole displays excellent activity against most anaerobic bacteria, including Bacteroides, Clostridium, Fusobacterium, Peptococcus, Peptostreptococcus, and Eubacterium. It is less active against Gardnerella and Helicobacter, and the gram-positive anaerobes Actinomyces, Propionibacterium, and Lactobacillus are typically resistant. It lacks activity against aerobic bacteria. Acquired resistance is uncommon. In the case of Bacteroides spp., metronidazole resistance has been linked to a family of nitroimidazole (nim) resistance genes that can be encoded chromosomally or episomally. These nim genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminonitroimidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing.

**Therapeutic Uses and Dosage**

Metronidazole is a relatively inexpensive and versatile drug with efficacy against a broad spectrum of anaerobic bacteria. Typical doses are 250–500 mg three times daily, via the intravenous or oral routes. The drug is frequently given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole is used as a component of prophylaxis for colorectal surgery and is employed as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with H. pylori (see Chapter 49). Metronidazole is used as therapy for mild-to-moderate C. difficile infection, although vancomycin is more effective for severe disease.

**Bacitracin**

Bacitracin is an antibiotic produced by the Tracy-I strain of B. subtilis. The bacitracins are a group of polypeptide antibiotics. The commercial products have multiple components; the major constituent is bacitracin A. A unit of the antibiotic is equivalent to 26 μg of the USP standard.

**Antimicrobial Activity, Mechanism of Action, and Resistance**

Bacitracin inhibits the synthesis of the bacterial cell wall; a variety of gram-positive cocci and bacilli, Neisseria, H. influenzae, and T. pallidum, are sensitive to the drug at 0.1 unit/mL or less. Actinomyces and Fusobacterium are inhibited by concentrations of 0.5–5 units/mL.
Enterobacteriaceae, *Pseudomonas*, *Candida* spp., and *Nocardia* are resistant to the drug. Few data are available on bacitracin resistance.

### Therapeutic Uses and Dosage

Current use is restricted to topical application. Bacitracin is available in ophthalmic and dermatomic ointments; the antibiotic also is available as a powder for the extemporaneous compounding of topical solutions.

A number of topical preparations of bacitracin, to which neomycin or polymyxin or both have been added, are available. For open infections, such as infected eczema and infected dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. Bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected cornal ulcer, when caused by susceptible bacteria, respond well to the topical use of bacitracin. Bacitracin has been used with limited success for eradication of nasal carriage of *Staphylococcus*.

### Adverse Effects

Nephrotoxicity results from the parenteral use of bacitracin.

### Mupirocin

Mupirocin is an antibiotic first isolated from *Pseudomonas fluorescens*. It is a mixture of several pseudomonic acids and is effective against gram-positive bacteria.

### Antimicrobial Activity, Mechanism of Action, and Resistance

Mupirocin is for topical use only. The drug is bactericidal against many gram-positive and selected gram-negative bacteria. It has good activity against *S. pyogenes*, MSSA, and MRSA. Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl tRNA synthase. There is no cross-resistance with other classes of antibiotics. High-level resistance is mediated by a plasmid, which encodes a “bypass” Ile tRNA synthase that binds mupirocin poorly.

### Therapeutic Uses and Dosage

Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*. The nasal ointment is approved for eradication of *S. aureus* nasal carriage. The consensus is that patients who stand to benefit from mupirocin prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for distant infection or a history of skin or soft-tissue infections (Perl et al., 2002).

### Adverse Effects

Mupirocin may cause irritation and sensitization at the site of application. Contact with the eyes causes irritation that may take several days to resolve. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate-to-severe renal failure to avoid accumulation of polyethylene glycol.

### Acknowledgment

Henry F. Chambers contributed to this chapter in previous editions of this book. We have retained some of his text in the current edition.

### Drug Facts for Your Personal Formulary: Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents

| Tetracycline (IV, PO) | • Inflammatory acne  
• Use for other indications has largely been replaced by doxycycline | • Good activity vs. rickettsiae, *Chlamydia*, *Mycoplasma*, *Legionella*, *Ureaplasma*, *Borrella*, *Francisella tularensis*, *Pasteurella multocida*, *Bacillus anthracis*, *Helicobacter pylori*  
• Some activity vs. *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Haemophilus influenzae*  
• Good CSF penetration  
• Renal excretion  
• Renal toxicity, hepatotoxicity at high doses |
| Doxycycline (IV, PO) | • Community-acquired pneumonia  
• Skin/soft-tissue infection  
• Urogenital chlamydia  
• Lymphogranuloma venereum  
• Syphilis (penicillin alternative)  
• Rocky Mountain spotted fever  
• Anthrax, tularemia  
• Lyme disease, leptospirosis | • Similar to tetracycline, with improved activity vs. streptococci and staphylococci  
• Good CSF penetration  
• Dual renal/biliary elimination  
• Preferred tetracycline for most indications due to more favorable activity, tolerability, and frequency of administration |
| Minocycline (IV, PO) | • Skin/soft-tissue infections  
• Mycobacterial infections  
• Nocardiosis | • Similar to doxycycline, with improved activity vs. staphylococci, *Acinetobacter*, and *Stenotrophomonas maltophilia*  
• Renal elimination  
• Vestibular toxicity |
| Tigecycline (IV) | • Intra-abdominal infection  
• Skin and soft-tissue infection  
• Pneumonia  
• Increased risk of death in pooled analysis; reserve as alternative therapy | • Similar to minocycline, with improved activity vs. *Escherichia coli*, *Klebsiella*, enterococci, *Bacteroides fragilis*  
• Wide distribution with low serum levels  
• Hepatic elimination |
### Chloramphenicol—Inhibitor of Bacterial Protein Synthesis

**General:** Bacteriostatic; dose-dependent bone marrow suppression, idiosyncratic fatal aplastic anemia, fatal "gray baby syndrome" in neonates receiving high doses

| Mupirocin (topical) | • Treatment of minor skin infections  
  • Eradication of nasal carriage of S. aureus | • Activity against broad array of gram-positive and gram-negative organisms  
  • May cause irritation at site of application |
Mycobacteria have caused epic diseases: TB and leprosy have terrorized humankind since antiquity. Although the burden of leprosy has decreased, TB is still the most important infectious killer of humans. Mycobacterium tuberculosis has now been called a new “antibiotic” nightmare because of its tenacity, lack of response to combination antibiotics, and a nearly universal propensity to develop acquired drug resistance. Mycobacterium abscessus has now been called a new “antibiotic” nightmare because of its tenacity, lack of response to combination antibiotics, and a nearly universal propensity to develop acquired drug resistance. Mycobacterium avium-intracellulare (or MAC) infection continues to be difficult to treat, mainly due to three natural barriers:

- **Cell wall.** Mycobacterium, from the Greek mycos, refers to mycobacteria’s waxy appearance, which is due to the composition of the cell walls. More than 60% of the cell wall is lipid, mainly mycolic acids composed of 2-branched, 3-hydroxy fatty acids with chains made of 76–90 carbon atoms! This extraordinary shield prevents many pharmacological compounds from getting to the bacterial cell membrane or inside the cytosol.

- **Efflux pumps.** A second layer of defense comes from an abundance of efflux pumps in the cell membrane. These transport proteins pump out potentially harmful chemicals from the bacterial cytoplasm back into the extracellular space and are responsible for the native resistance of mycobacteria to many standard antibiotics (Morris et al., 2005). As an example, ABC permeases comprise a full 2.5% of the genome of Mycobacterium tuberculosis.

- **Location in host.** A third barrier is the propensity of some of the bacilli to hide inside the patient’s cells, thereby surrounding themselves with an extra physicochemical barrier that antimicrobial agents must cross to be effective.

Mycobacteria are defined by their rate of growth on agar as rapid and slow growers (see list in Table 60–1). Rapid growers are visible to the naked eye within 7 days; slow growers are visible later. Slow growers tend to be susceptible to antibiotics specifically developed for mycobacteria, whereas rapid growers tend to be also susceptible to antibiotics used against many other bacteria. Recent evidence suggests that in countries such as the U.S., Mycobacterium abscessus now accounts for 80% of rapid growers from the respiratory system (Griffith et al., 2007). The pharmacology of drugs developed against slow growers is discussed in this chapter. However, rapid growers tend to be treated with antibiotics used to treat nonmycobacteria, such as macrolides, aminoglycosides, quinolones, and β-lactams, whose pharmacology is discussed in Chapters 56–59.

The mechanisms of action of the antmycobacterial drugs are summarized in Figure 60–1. The mycobacterial mechanisms of resistance to these drugs are summarized in Figure 60–2. The model termed the antibiotic resistance arrow of time has combined these mechanisms in an arrow of time, starting with early induction of efflux pumps that leads to chromosomal mutations in drug target proteins and efflux

Rifampin enters bacilli in a concentration-dependent manner, achieving steady-state concentrations within 15 min (Gumbo et al., 2007). Rifampin binds to the β subunit of DNA-dependent RNA polymerase (RpoB) to form a stable drug-enzyme complex. Drug binding suppresses chain formation in RNA synthesis.

Antimycobacterial Drugs

Rifamycins: Rifampin, Rifapentene, and Rifabutin

Rifamycins are macrocyclic antibiotics. Rifampin or rifampicin, rifapentine, and rifabutin are macrocyclic antibiotics important in the treatment of mycobacterial diseases.

Mechanism of Action

The mechanism of action for rifamycins is typified by rifampin’s action against M. tuberculosis. Rifampin enters bacilli in a concentration-dependent manner, achieving steady-state concentrations within 15 min (Gumbo et al., 2007). Rifampin binds to the β subunit of DNA-dependent RNA polymerase (RpoB) to form a stable drug-enzyme complex. Drug binding suppresses chain formation in RNA synthesis.

Slow growers tend to be susceptible to antibiotics specifically developed for Mycobacteria. Rapid growers tend to be susceptible to antibiotics also used against many other bacteria.

**Antibacterial Activity**

Rifampin inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms, such as Escherichia coli, Pseudomonas, indole-positive and indole-negative Proteus, and Klebsiella. Rifampin is very active against Staphylococcus aureus and coagulase-negative staphylococci. The drug also is highly active against Neisseria meningitidis and Haemophilus influenzae. Rifampin inhibits the growth of Legionella species in cell culture and in animal models.

Rifampin inhibits the growth of many M. tuberculosis clinical isolates in vitro at concentrations of 0.06–0.25 mg/L (Heifets, 1991). Rifampin is also bactericidal against Mycobacterium leprae. Mycobacterium kansasii is inhibited by 0.25–1 mg/L. Most strains of Mycobacterium scrofulaceum, Mycobacterium intracellulare, and Mycobacterium avium are suppressed by concentrations of 4 mg/L. Mycobacterium abscessus inactivates rifampin via an ADP-ribosyltransferase and monoxygenase, making the bacteria innately resistant to rifampicins (Nessar et al., 2012). Rifapentine MICs are similar to those of rifampin. Rifabutin inhibits the growth of most MAC isolates at concentrations ranging from 0.25 to 1 mg/L. Rifabutin also inhibits the growth of many strains of M. tuberculosis at concentrations of 0.125 mg/L or less and in vitro has better MICs than rifampin.

**Bacterial Resistance**

The prevalence of rifampin-resistant isolates (1 in every 10^7 to 10^8 bacilli) is due to an alteration of the target of this drug, rpoB, with resistance in 86% of cases due to mutations at codons 526 and 531 of the rpoB gene (Somoskovi et al., 2001). Rifamycin mono-resistance occurs at higher rates when patients with AIDS and multicavitary TB are treated with either rifapentine or rifabutin (Burman et al., 2006). Efflux pump induction, and mutations in efflux pumps, have now been demonstrated to be associated with rifamycin resistance (Li et al., 2015).

**ADME**

After oral administration, the rifamycins are absorbed to variable extents (Table 60–2) (Burman et al., 2001). Food decreases the rifampin Cmax by one-third; a high-fat meal increases the AUC of rifampicin by 50%. Food has no effect on rifabutin absorption. Thus, rifampin should be taken on an empty stomach, whereas rifapentine should be taken with food if possible.
Rifamycins are metabolized by microsomal B-esterases and cholinesterases. A major pathway for rifabutin elimination is CYP3A. Due to autoinduction, all three rifamycins reduce their own AUCs with repeated administration (Table 60–3). They have good penetration into many tissues, but peak concentration and AUCs in the CNS and pericardial fluid reach only about 13%–20% of those in plasma (Nau et al., 1992; Shenje et al., 2015). The drugs and metabolites are excreted by bile and eliminated via feces, with urine elimination accounting for only one-third and less of metabolites.

The population PK of rifampin are best described using a one-compartment model with transit compartment absorption (Wilkins et al., 2008), using the PK parameters in Table 60–2. Rifapentine PK are likewise best described using a one-compartment open model with first-order absorption and elimination (Langdon et al., 2005). The PK parameters are summarized in Table 60–2. However, for each 1-kg weight increase above 50 kg, systemic clearance increases by 0.05 L/h and $V_d$ by 0.69 L. Thus, $C_{P_{\text{max}}}$ and AUC decrease with increasing patient weight above 50 kg.

In contrast, rifabutin PK are best described by a two-compartment open model with first-order absorption and elimination. Rifabutin disposition is biexponential. Rifabutin concentrations are substantially higher in tissue than in plasma due to its lipophilic properties, leading to the very high

---

Figure 60–1  Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections. Approved drugs for the chemotherapy of mycobacterial diseases may be grouped according to the sites of action indicated by the pictures above that expand regions of the mycobacterium: inhibitors of nucleic acid and protein synthesis; disruptors of cell wall and cell membrane synthesis; inhibitors of membrane transport. Specific antimycobacterial agents and their mechanisms of action are also listed. Rifamycin is used as a generic term for several drugs, of which rifampin is used most frequently. Clofazimine, whose mode of action is not understood, is omitted.

Rifamycins are metabolized by microsomal B-esterases and cholinesterases. A major pathway for rifabutin elimination is CYP3A. Rifampin’s bactericidal and sterilizing effect activity are best optimized by high AUCs and a high AUC/MIC ratio (Gumbo et al., 2007a; Pasipanodya et al., 2013). However, resistance suppression and rifampin’s enduring postantibiotic effect are best optimized by high \( C_{max} / \text{MIC} \). Therefore, the duration of time that the rifampin concentration persists above the MIC is of less importance. This means that the \( t_{1/2} \) of a rifamycin is less of an issue in optimizing therapy, and that if patients could tolerate it, higher doses would lead to higher bactericidal activities while suppressing resistance. Recent clinical trials have confirmed better sputum bacillary decline with up to 3.5 times higher rifampin doses than currently used, which would increase both AUC/MIC and \( C_{max} / \text{MIC} \) nonlinearly (Boeree et al., 2015). Currently, these larger rifampin doses are in phase III trials.

**Therapeutic Uses**

Rifampin for oral administration is available alone and as a fixed-dose combination with isoniazid (150 mg isoniazid, 300 mg rifampin) or with isoniazid and pyrazinamide (50 mg isoniazid, 120 mg rifampin, and 300 mg pyrazinamide). A parenteral form of rifampin is also available. The dose of rifampin for treatment of TB in adults is 600 mg, given once daily, either 1 h before or 2 h after a meal. Children should receive 15 mg/kg (range 10–20 mg/kg), with the maximum dose 600 mg/d, given in the same way. Rifabutin is administered at 5 mg/kg/d and rifapentine at 10 mg/kg once a week.

Rifampin is also useful for the prophylaxis of meningococcal disease and *H. influenzae* meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children older than 1 month should receive 10–15 mg/kg, to a maximum of 600 mg. Combined with a β-lactam antibiotic or vancomycin,
rifampin may be useful for therapy in selected cases of staphylococcal endocarditis or osteomyelitis, especially those caused by staphylococci “tolerant” to penicillin. Rifampin may also be indicated for the eradication of the staphylococcal nasal carrier state in patients with chronic furunculosis. In the treatment of brucellosis, 900 mg a day rifampin can be combined with doxycycline for 6 weeks.

**Untoward Effects**

Rifampin is generally well tolerated in patients. Usual doses result in less than 4% of patients with TB developing significant adverse reactions; the most common are rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%). Rarely, hepatitis and deaths due to liver failure have been observed in patients who received other hepatotoxic agents in addition to rifampin or who had preexisting liver disease. Chronic liver disease, alcoholism, and old age appear to increase the incidence of severe hepatic problems. GI disturbances have occasionally required discontinuation of the drug. Various nonspecific symptoms related to the nervous system also have been noted.

Hypersensitivity reactions may be encountered. High-dose rifampin should not be administered on a dosing schedule of less than twice weekly because this is associated with a flu-like syndrome of fever, chills, and myalgias in 20% of patients so treated. The syndrome also may include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock. Light chain proteinuria has also been documented with rifampin use. Thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. Because the potential teratogenicity of rifampin is unknown and the drug is known to cross the placenta, it is best to avoid the use of this agent during pregnancy.

Rifabutin is generally well tolerated; primary reasons for discontinuation of therapy include rash (4%), GI intolerance (3%), and neutropenia (2%) (Nightingale et al., 1993). Neutropenia occurred in 25% of patients with severe HIV infection who received rifabutin. Uveitis and arthralgias have occurred in patients receiving rifabutin doses greater than 450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur. Rifabutin causes an orange-tan discoloration of skin, urine, feces, saliva, tears, and contact lenses, like rifampin. Rarely, thrombocytopenia, a flu-like syndrome, hemolytic anemia, myositis, chest pain, and hepaticitis develop in patients treated with rifabutin. Unique side effects include polymyalgia, pseudojaundice, and anterior uveitis.

**Rifamycin Overdose**

Rifampin overdose is uncommon. The most prominent symptoms are the orange discoloration of skin, fluids, and mucosal surfaces, leading to the term *red-man syndrome*. Overdose can be life threatening. Treatment consists of supportive measures; there is no antidote.

**Drug Interactions**

Because rifampin potently induces CYPs 1A2, 2C9, 2C19, and 3A4, its administration results in a decreased 1/2 of the AUC of many compounds that are metabolized by these CYPs. Rifabutin is a less-potent inducer of CYPs than rifampin; however, rifabutin does induce hepatic microsomal enzymes and decreases the 1/2 of zidovudine, prednisone, digoxin, quinidine, ketoconazole, propranolol, phenytoin, sulfonylureas, and warfarin. It has less effect than rifampin on serum levels of indinavir and nelfinavir.

Compared to rifabutin and rifampin, the CYP-inducing effects of rifabutin are intermediate.

**Pyrazinamide**

Pyrazinamide is the synthetic pyrazine analogue of nicotinamide. Pyrazinamide is also known as pyrazinoic acid amide, pyrazine carboxyamide, and pyrazincarboxamide. Pyrazinamide was first synthesized at Merck in 1936 in Germany but was first examined as an anti-TB agent in 1952.

**Mechanism of Action**

Pyrazinamide is activated by acidic conditions. Several mechanisms of action have been proposed. In one model, pyrazinamide passively diffuses into mycobacterial cells, in which *M. tuberculosis* pyrazinamidase (encoded by the pncA gene) deaminates pyrazinamide to pyrazinoic acid (POA, its dissociated form), which is then followed by passive diffusion of the POA to the extracellular milieu (Zhang et al., 1999). In an acidic extracellular milieu, a fraction of POA is protonated to the uncharged form, POAH, a more lipid-soluble form that reenters the bacillus and accumulates due to a deficient efflux pump. The Henderson-Hasselbalch equation (Chapter 2) progressively favors the formation of POAH and its equilibration across membranes as the pH of the extracellular medium declines toward the pKₐ of pyrazinoic acid, 2.9. The acidification of the intracellular milieu is believed to inhibit enzyme function and collapse the transmembrane proton motive force, thereby killing the bacteria. Inhibitors of energy metabolism or reduced energy production states lead to enhanced pyrazinamide effect (Zhang et al., 2014). A specific target of pyrazinamide has been proposed to be ribosomal protein S1 (encoded by RpsA) in the trans-translation process, so that toxic proteins due to stress accumulate and kill the bacteria (Shi et al., 2011). In addition, pyrazinamide’s target may include an aspartate decarboxylase (encoded by panD) involved in making precursors needed for pantothenate and CoA biosynthesis in persistent *M. tuberculosis* (Zhang et al., 2013).

**Antibacterial Activity**

Pyrazinamide exhibits antimicrobial activity in vitro only at acidic pH. At pH 5.9, 95% of clinical isolates have an MIC of 6.25–200 mg/L (Gumbo et al., 2014).

**Mechanisms of Resistance**

Pyrazinamide-resistant *M. tuberculosis* expresses pyrazinamidase with reduced affinity for pyrazinamide. This reduced affinity decreases the conversion of pyrazinamide to POA. Single point mutations in the pncA gene are encountered in some clinical isolates. In addition, mutations in the genes encoding proposed pyrazinamide targets of RpsA and panD are encountered in pyrazinamide resistance (Zhang et al., 2014). Finally, it has been demonstrated that the efflux rate of POA predicts pyrazinamide resistance with greater than 93% sensitivity and specificity, suggesting a role for efflux pumps in this drug’s resistance (Zimic et al., 2012).

**ADME**

The oral bioavailability of pyrazinamide exceeds 90%. GI absorption segregates patients into two groups: fast absorbers (56%), with an absorption rate constant of 3.56/h, and slow absorbers (44%), with an absorption rate of 1.25/h (Wilkins et al., 2006). The drug is concentrated 20-fold in lung epithelial lining fluid (Conte et al., 2000). Pyrazinamide is metabolized by microsomal deamidase to POA and subsequently hydroxylated to 5-hydroxy-POA, which is then excreted by the kidneys. CL (clearance) and V₆ (volume of distribution) increase with patient mass (0.5 L/h and 4.3 L for every 10 kg above 50 kg), and V₆ is larger in males (by 4.5 L) (see Table 60–2). This has several implications. The t₁/₂ of pyrazinamide will vary considerably based on weight and gender, and the AUC₁₂₄ will decrease with increase in weight for the same dose (same mg drug/kg body weight). Pyrazinamide clearance is reduced in renal failure; therefore, the dosing frequency is reduced to three times a week at low glomerular filtration rates. Hemodialysis removes pyrazinamide; therefore, the drug needs to be redosed after each session of hemodialysis (Malone et al., 1999b).

**Microbial Pharmacokinetics-Pharmacodynamics**

Pyrazinamide’s sterilizing effect is closely linked to AUC₁₂₄/MIC (Chigutsa et al., 2015; Gumbo et al., 2009). Such clinical parameters as relapse, cure at the end of therapy, and patient death have been confirmed to be predicted by the AUC₁₂₄ and by the MIC (Gumbo et al., 2014; Pasipanodya et al., 2013).

**Therapeutic Uses**

The coadministration of pyrazinamide with isoniazid or rifampin has led to a one-third reduction in the duration of anti-TB therapy and a
two-thirds reduction in TB relapse. This led to reduction in length of therapy to 6 months, producing the current "short-course" chemotherapy. Pyrazinamide is administered at an oral dose of 35 mg/kg (30–40) mg/kg/d.

**Untoward Effects**

Injury to the liver is the most serious side effect of pyrazinamide. When a dose of 40–50 mg/kg is administered orally, signs and symptoms of hepatic disease appear in about 15% of patients, with jaundice in 2%–3% and death due to hepatic necrosis in rare instances. Current regimens employed (15–30 mg/kg/d) are much safer. Prior to pyrazinamide administration, all patients should undergo studies of hepatic function, and these studies should be repeated at frequent intervals during the entire period of treatment. If evidence of significant hepatic damage becomes apparent, therapy must be stopped. Pyrazinamide should not be given to individuals with hepatic dysfunction unless this is absolutely unavoidable.

In nearly all patients, pyrazinamide inhibits excretion of urate, resulting in hyperuricemia, which may cause acute episodes of gout. Other untoward effects observed with pyrazinamide include arthralgias, anorexia, nausea and vomiting, dysuria, malaise, and fever. In the U.S., the use of pyrazinamide is not approved during pregnancy because of inadequate data on teratogenicity.

**Isoniazid**

Isoniazid (isonicotinic acid hydrazide), also called INH (Figure 60–3), is an important drug for the chemotherapy of drug-susceptible TB. All patients infected with isoniazid-sensitive strains of the tubercle bacillus receive the drug if they can tolerate it. The use of combination therapy to 10 (1 × 10^6) bacilli. Because TB resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants can be selected and amplified by isoniazid monotherapy. Thus, two or more agents are usually used. Because the mutations resulting in drug resistance are independent events, the probability of resistance to two antimycobacterial agents is small, about 1 in 10^10, a low probability considering the number of bacilli involved.

**Mechanisms of Resistance**

The prevalence of drug-resistant mutants is about 1 in 10^6 bacilli. Because TB cavities may contain as many as 10^2 to 10^3 microorganisms, preexistent resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants can be selected and amplified by isoniazid monotherapy. Thus, two or more agents are usually used. Because the mutations resulting in drug resistance are independent events, the probability of resistance to two antimycobacterial agents is small, about 1 in 10^2 (1 × 10^6 × 10^6), a low probability considering the number of bacilli involved.

Resistance to INH is associated with mutation or deletion of KatG, overexpression of the genes for InhA (confers low-level resistance to INH

**Metabolism and activation of isoniazid.** The prodrug isoniazid is metabolized in humans by NAT2 isoforms to its principal metabolite, N-acetyl isoniazid, which is excreted by the kidney. Isoniazid diffuses into mycoplasma, where it is "activated" by KatG (oxidase/peroxidase) to the nicotinoyl radical. The nicotinoyl radical reacts spontaneously with NAD^+ to produce adducts that inhibit essential enzymes in synthesis of the cell wall and with NADP^+ to produce an inhibitor of nucleic acid synthesis.
and some cross-resistance to ethionamide), and altpC and mutations in the kasA and katG genes. KatG mutants exhibit a high level of resistance to isoniazid. The most common mechanism of isoniazid resistance in clinical isolates is due to single point mutations in the heme-binding catalytic domain of KatG, especially a serine-to-asparagine change at position 315. Although isolates with this mutation completely lose the ability to form nicotinoyl-NAD+/NADP+ adducts, they retain good catalase activity and maintain good biofitness. Compensatory mutations in the altpC promoter occur and increase survival of KatG mutant strains under oxidative stress. Efflux pump induction by isoniazid has been demonstrated, and it also confers resistance to ethambutol (Colangeli et al., 2005). In an in vitro pharmacodynamic model, efflux pump-induced resistance developed within 3 days and was followed by development of katG mutations (Gumbo et al., 2007b).

**ADME**

The bioavailability of orally administered isoniazid is about 100% for the 300-mg dose. The PK of isoniazid are best described by a two-compartment model, with the PK parameters in Table 60–2 (Pasipanodya et al., 2013). The ratio of isoniazid in the epithelial lining fluid to that in plasma is 1–2 and for CSF is 0.9 (Conte et al., 2002). Approximately 10% of drug is bound to protein. From 75% to 95% of a dose of isoniazid is excreted in the urine within 24 h, mostly as acetylisoniazid and isonicotinic acid.

Isoniazid is metabolized by hepatic arylamine NAT2, encoded by a variety of NAT2 alleles (Figure 60–3). Isoniazid clearance in patients has been traditionally classified as one of two phenotypic groups: “slow” and “fast” acetylators, as seen in Figure 60–4. Recently, the phenotypic groups have been expanded to fast, intermediate, and slow acetylators, and population PK parameters of isoniazid have been estimated and related to NAT2 genotype, and the number of NAT2*4 alleles accounts for 88% of the variability of isoniazid clearance.

The frequency of each acetylation phenotype depends on race but is not influenced by sex or age. Fast acetylation is found in Inuit and Japanese. Slow acetylation is the predominant phenotype in most Scandinavians, Jews, and North African whites. The high acetyltransferase activity (fast acetylation) is inherited as an autosomal dominant trait; fast acetylators of isoniazid are either heterozygous or homozygous.

**Microbial Pharmacokinetics-Pharmacodynamics**

Isoniazid’s microbial kill, as well as resistance emergence, is best explained by the ratios of AUC_{INF} to MIC and C_{max}/MIC (Gumbo et al., 2007c; Pasipanodya et al., 2013). Because AUC is proportional to dose/CL, this means that efficacy is most dependent on drug dose and CL and thus on the activity of NAT2 polymorphic forms. Thus, rapid acetylators are more likely to have reduced microbial cure, increased relapse, and increased acquired resistance (Pasipanodya et al., 2012).

**Therapeutic Uses**

Isoniazid is available as a pill, as an elixir, and for parenteral administration. The recommended total daily dose of isoniazid is 5 mg/kg with a maximum of 300 mg administered daily or 10 mg/kg (range 10–15 mg/kg with a maximum of 900 mg) two or three times a week; oral and intramuscular doses are identical.

**Untoward Effects**

After NAT2 converts isoniazid to acetylisoniazid, which is excreted by the kidney, acetylsalicylic acid can also be converted to acetylsalicylic acid (Roy et al., 2008) and then to hepatotoxic metabolites by CYP2E1. Alternatively, acetylsalicylic acid may be further acetylated by NAT2 to diacetylsalicylic acid, which is nontoxic. In this scenario, rapid acetylators will rapidly remove acetylsalicylic acid, while slower acetylation or induction of CYP2E1 will lead to more of the toxic metabolites. Rifampin is a potent inducer of CYP2E1, which is why it potentiates isoniazid hepatotoxicity.

Elevated serum aspartate and alanine transaminases are encountered commonly in patients on isoniazid. However, the enzyme levels often normalize even when isoniazid therapy is continued (Blumberg et al., 2003). Severe hepatic injury occurs in about 0.1% of all patients taking the drug. Hepatic damage is rare in patients less than 20 years old, but the incidence increases with age. Overall risk is increased to about 3% by coadministration with rifampin. Most cases of hepatitis occur 4–8 weeks after the start of therapy.

If pyridoxine is not given concurrently, peripheral neuritis (most commonly paresthesias of feet and hands) is encountered in about 2% of patients receiving 5 mg/kg isoniazid daily. Neuropathy is more frequent in slow acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. Other neurological toxicities include convulsions in patients with seizure disorders, optic neuritis and atrophy, muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy. Mental abnormalities may appear during the use of this drug, including euphoria, transient impairment of memory, loss of self-control, and florid psychoses.

Patients may develop hypersensitivity to isoniazid. Hematological reactions also may occur. Vasculitis associated with antinuclear antibodies may appear during treatment but disappears when the drug is stopped. Arthritic symptoms have been attributed to this agent. Miscellaneous reactions associated with isoniazid therapy include dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. In persons predisposed to pyridoxine deficiency anemia, the administration of isoniazid may result in dramatic anemia. Treatment of the anemia with large doses of vitamin B6 gradually returns the blood count to normal. A drug-induced syndrome resembling systemic lupus erythematosus has also been reported.

**Isoniazid Overdose**

As little as 1.5 g of isoniazid can be toxic. Isoniazid overdose has been associated with the clinical triad of

- Seizures refractory to treatment with phenytoin and barbiturates
- Metabolic acidosis with an anion gap that is resistant to treatment with sodium bicarbonate
- Coma

![Figure 60–4](image-url) Multi-modal distribution of INH clearance due to NAT2 polymorphisms. A group of matched male volunteers received INH (250 mg orally), and the time of plasma disappearance was determined. One-third of the subjects had INH elimination values above 1.5 h; these were the fast acetylators. Two-thirds had values ranging from 2.1 to 4.0 h, with a suggestion of multiple groups; these were the slow acetylators. Plots of the mean data (C vs. time after administration) demonstrate the PK effects of acetylation rate. Both groups reached C_{max} at 1 h. The slow acetylators (red line) achieved a higher C (4 µg/mL) with a mean elimination t_{1/2} of 3.0 h; the fast acetylators (green line) reached a lower maximal C (2 µg/mL) with a mean elimination t_{1/2} of 1.0 h. The acetylation rate reflects variable expression of active polymorphic forms of NAT2. Slow acetylators may be a greater risk for adverse effects from INH, sulfonamides, and procarcinoids; fast acetylators may have diminished responses to standard doses of these agents but greater risk from bioactivation by NAT2 of arylamine/hydrazine carcinogens. Recently, researchers have identified three elimination subgroups for INH metabolism: fast, slow, and intermediate (codominant fast and slow alleles).
Mechanisms of Resistance

In vitro, mycobacterial resistance to the drug develops via mutations in the embB gene. In 30%–70% of clinical isolates that are resistant to ethambutol, mutations are encountered at codon 306 of the embB gene. However, mutations in this codon are also encountered in ethambutol-susceptible mycobacteria, as though this mutation is necessary, but not sufficient, to confer ethambutol resistance (Safi et al., 2008). Enhanced efflux pump activity may induce resistance to both isoniazid and ethambutol in vitro.

ADME

The oral bioavailability of ethambutol is about 80%. Approximately 10%–40% of the drug is bound to plasma protein. Ethambutol drug concentrations have been modeled using a two-compartment open model, with first-order absorption and elimination (Zhu et al., 2004). The decline in ethambutol is biexponential, with a $t_1/2$ of 3 h in the first 12 h and a $t_1/2$ of 9 h between 12 and 24 h due to redistribution of drug. Clearance and $V_d$ are greater in children than in adults on a per kilogram basis. Slow and incomplete absorption is common in children, so that good peak concentrations of drug are often not achieved with standard dosing (Zhu et al., 2004). See Table 60–2 for PK data on this drug.

About 80% of the drug is not metabolized at all and is renally excreted. Therefore, in renal failure ethambutol should be dosed at 15–25 mg/kg three times a week instead of daily, even in patients receiving hemodialysis. The remainder of ethambutol (~20%) is oxidized by aldehyde dehydrogenase and excreted as aldehyde and dicarboxylic acid derivatives.

Microbial Pharmacokinetics-Pharmacodynamics

Ethambutol’s microbial kill of $M. tuberculosis$ is optimized by $AUC/MIC$, while that against disseminated MAC is optimized by $C_{ss}/MIC$ (Deshpande et al., 2010). Thus, to optimize microbial kill, high intermittent doses such as 25 mg/kg every other day to 50 mg/kg twice a week may be superior to daily doses of 15 mg/kg.

Therapeutic Uses

Ethambutol is available for oral administration in tablets containing the D-isomer. It is used for the treatment of TB, disseminated MAC, and in $M. kansasi$ infection. Ethambutol is administered at 20 mg/kg (15–25 mg/kg) per day for both adults and children.

Untoward Effects

Ethambutol produces very few serious untoward reactions: About 1% experience diminished visual acuity, 0.5% a rash, and 0.3% drug fever. Other side effects that have been observed are pruritus, joint pain, GI upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations. Therapy with ethambutol results in an increased concentration of urate in the blood in about 50% of patients, owing to decreased renal excretion of uric acid.

The most important side effect is optic neuritis, resulting in decreased visual acuity and loss of red-green discrimination. The incidence of this reaction is proportional to the dose of ethambutol and is observed in 15% of patients receiving 50 mg/kg/d, in 5% of patients receiving 25 mg/kg/d, and in less than 1% of patients receiving daily doses of 15 mg/kg. The intensity of the visual difficulty is related to the duration of therapy after the decreased visual acuity first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are thus recommended. Recovery usually occurs when ethambutol is withdrawn. Drug interactions involving ethambutol are not significant.

Oxazolidinones: Linezolid, Tedizolid, and Sutezolid

Oxazolidinones have been in clinical use for over a decade for the treatment of gram-positive cocci. Linezolid and tedizolid have been found to be highly efficacious in the treatment of TB. Several studies have examined the utility of linezolid for the treatment of MDR-TB. The first study enrolled 41 patients with MDR-TB, who were immediately assigned to linezolid therapy without change of background regimen, or to a delay of 2 months (Lee et al., 2012). By month 4, 79% in the immediate-start group had sputum culture conversion compared to 35%
in the delayed-start group. However, 4 of every 5 patients had significant adverse events. In a randomized controlled trial of 65 patients with MDR-TB, linezolid therapy was associated with a 79% sputum conversion at 24 months compared to 38% among controls (Tang et al., 2015). However, 82% developed adverse events.

In a recent meta-analysis of 12 studies, Sotgiu et al. (2012) found that 94% of patients on linezolid achieved sputum conversion over an average period of 61 days; however, 68% developed major adverse events. Thus, linezolid is associated with extremely high sputum conversion rates, but at a price of a high rate of adverse events. As a result, studies are examining other oxazolidinones, such as tedizolid and netizolid, the latter drug specifically designed for the treatment of TB. It is hoped these will have the same efficacy, but with fewer side effects. The pharmacology of oxazolidinones is discussed in Chapter 59.

Aminoglycosides: Streptomycin, Amikacin, and Kanamycin

The aminoglycosides streptomycin, amikacin, and kanamycin are used in the treatment of mycobacterial diseases. The MICs for *M. tuberculosis* in Middlebrook broth are 0.25–3.0 mg/L for all three aminoglycosides. For *M. avium*, streptomycin and amikacin MICs are 1–8 mg/L; those of kanamycin are 3–12 mg/L. *Mycobacterium kansasii* is frequently susceptible to these agents, but other nontuberculous mycobacteria are only occasionally susceptible. As an example, for amikacin in treatment of *M. abscessus*, an MIC range of 2–128 mg/L has been noted (Ferro et al., 2016). The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in Chapter 58.

Bacterial Resistance

Primary resistance to streptomycin is found in 2%–3% of *M. tuberculosis* clinical isolates. Resistance to aminoglycosides involves several genetic loci, as well as efflux pumps. Aminoglycosides inhibit protein synthesis by binding to the 30S ribosomal subunit and causing misreading of the genetic code during translation. The 30S ribosomal unit is made of the 16S mRNA (encoded by *rpsL*), which binds to the ribosomal protein S12 (encoded by *rrs*) to optimize tRNA binding and mRNA decoding. Mutations in *rpsL* and *rrs* are associated with high-level aminoglycoside resistance in mycobacteria. However, mutations in these genes are only encountered in half of clinical isolates with aminoglycoside resistance. GidB is an rRNA methyltransferase for 16S rRNA, and mutations in the *gidB* gene are associated with low-level streptomycin-resistant mutants at a rate 2000 times that in wild type. Mutations in *gidB* are encountered in 33% of streptomycin-resistant clinical isolates of *M. tuberculosis*. Finally, efflux pump–mediated resistance was recently demonstrated in clinical isolates with low-level streptomycin-resistant *M. tuberculosis* and interacted with chromosomal mutations in *gidB* (Spies et al., 2008).

Therapeutic Uses

Therapeutic uses of aminoglycosides in treatment of mycobacterial infections are discussed further in the chapter.

Bicyclic Nitroimidazoles: Delamanid and Pretomanid

Pretomanid, discovered by Stover et al. in 2000, and delamanid, discovered by Matsumoto et al. in 2006, are bicyclic nitroimidazopyrans that are being used in the treatment of extensively drug-resistant and multidrug-resistant TB and are in clinical trials for use in drug-susceptible TB.

Mechanisms of Action

Pretomanid has two mechanisms of action. First, under aerobic conditions it inhibits *M. tuberculosis* mycolic acid and protein synthesis at the step between hydroxyisocoumarin and ketomycolate (Stover et al., 2000). Similar to the structurally related metronidazole, pretomanid is a prodrug that requires activation by the bacteria via a nitroreduction step that requires, among other factors, a specific G6PD, FGD1, and the reduced deazaflavin cofactor F \(_{\text{red}}\) encoded by *Rv3547* (Bashiri et al., 2008). Second, in NRPB, it generates reactive nitrogen species such as NO via its des-nitro metabolite, which then augment the kill of intracellular NRPB by the innate immune system (Singh et al., 2008). In addition, direct poisoning of the respiratory complex in the NRPB leads to ATP depletion.

Delamanid is also a prodrug that is activated by the same enzyme encoded by *Rv3547* (Xavier and Lakshmanan, 2014). Similarly, it also forms a reactive intermediate metabolite that inhibits mycolic acid production.

Antibacterial Activity

The MICs of pretomanid against *M. tuberculosis* range from 0.015 to 0.25 mg/L, but the drug lacks activity against other mycobacteria. Similarly, for delamanid, MICs range from 0.006 to 0.012 mg/L (Matsumoto et al., 2006).

Mechanism of Resistance

The proportion of mutants resistant to 5 mg/L of pretomanid is 10\(^{-4}\). Resistance arises due to changes in structure of FGD, which is due to a variety of point mutations in the *fgd* gene. However, resistant isolates have also been identified that lack *fgd* mutations, so that resistance may also be due to other mechanisms (Stover et al., 2000). Mutation frequencies for delamanid are unclear; however, resistance has also been shown to be due to *fgd1* and also *fbiA* mutations (Bloemberg et al., 2015).

ADME

The PK parameters of pretomanid include a clearance of 6.7–8.8 L/h at steady state, with a terminal *t_1/2* of 16–20 h, based on a noncompartmental analysis (Ginsberg et al., 2009). Similarly, no compartmental PK analyses have been published yet with delamanid, with noncompartmental PK published as an AUC\(_{0-\infty}\) of 7.9 mg·h/L after a dose of 100 mg twice a day and 11.8 mg·h/L after a 200 mg twice-a-day dose; *t_1/2* = about 38 h (Gler et al., 2012). Systemic exposures increase on uptake with food.

Microbial Pharmacokinetics-Pharmacodynamics

No formal microbial PK-pharmacodynamic work has been performed with delamanid. Pretomanid microbial kill is driven by percentage time concentration persists above MIC (Ahmad et al., 2011). The dose of 200 mg a day in humans achieves optimal PK-pharmacodynamic exposure in most patients.

Therapeutic Uses

Delamanid is currently dispensed in 50-mg tablets at 100 mg twice daily, with food. It is used in the treatment of multidrug-resistant TB and is being examined in combination with other drugs. Pretomanid is administered at 200 mg a day and is undergoing phase III trials in combination with other drugs for treatment of both drug-susceptible and drug-resistant TB.

Untoward Effects

Data on untoward effects are currently being gathered. It has been noted that delamanid is associated with QT segment prolongation; however, the clinical significance is unclear.

Clofazimine

Clofazimine is a fat-soluble riminophenazine dye.

Mechanism of Action

The biochemical basis for the antimicrobial actions of clofazimine remains to be established (Anonymous, 2008a). Possible mechanisms of action include membrane disruption, inhibition of mycobacterial phospholipase A, inhibition of microbial K\(^+\) transport, generation of hydrogen peroxide, interference with the bacterial electron transport chain, or efflux pump inhibition. However, it is known that clofazimine has both antibacterial activity and anti-inflammatory effects via inhibition of macrophages, T cells, neutrophils, and complement.

Antibacterial Activity

The MICs for *M. avium* clinical isolates are 1–5 mg/L. The MICs for *M. tuberculosis* are about 1.0 mg/L. The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*. It has activity against many gram-positive bacteria with an MIC of
Bacterial Resistance
Clofazimine-resistant Mycobacterium tuberculosis carries a mutation in the gene encoding a transcription repressor for efflux pump MmpL; this is associated with cross resistance to bedaquiline (Hartkoorn et al., 2014; Zhang et al., 2015).

ADME
Clofazimine is administered orally at doses up to 300 mg a day. Clofazimine’s oral bioavailability is 45%–60%; it is increased 2-fold by high-fat meals and decreased 30% by antacids (Niz et al., 2004). After a single dose, clofazimine is best modeled using a one-compartment model and has a prolonged absorption phase; after 200 mg of clofazimine, the t₁/₂ is 5.3–7.8 h. After prolonged repeated dosing, the t₁/₂ is about 70 days. For PK data, see Table 60–2. As a result of the good penetration into many tissues, a reddish-black discoloration of skin and body secretions may occur and take a long time to resolve. Crystalline deposits of the drug have been encountered in many tissues at autopsy (Anonymous, 2008a). Clofazimine is metabolized in the liver in four steps: hydrolytic dehalogenation, hydrolytic deamination, glucuronidation, and hydroxylation.

Untoward Effects
Gastrointestinal problems are encountered in 40%–50% of patients. In patients who have died following the abdominal pain, crystal deposition in intestinal mucosa, liver, spleen, and abdominal lymph nodes has been demonstrated (Anonymous, 2008a). Body secretion discoloration, eye discoloration, and skin discoloration occur in most patients and can lead to depression in some patients.

Drug Interactions
Anti-inflammatory effects may be inhibited by dapsone.

Fluoroquinolones
Fluoroquinolones are DNA gyrase inhibitors. Their chemistry, spectrum of activity, and pharmacology are discussed in detail in Chapter 56. Drugs such as ofloxacin and ciprofloxacin have been second-line anti-TB agents for many years, but they are limited by the rapid development of resistance. Adding C8 halogen and C8 methoxy groups markedly reduces the propensity for drug resistance. Of the C8 methoxy quinolones, moxifloxacin, gatifloxacin, and levofloxacin have been examined in the clinic for the treatment of pulmonary TB and meningeal TB.

Microbial Pharmacokinetics-Pharmacodynamics Relevant to TB
Fluoroquinolone microbial kill is best explained by the AUC₀–₂₄h/MIC ratio. In preclinical models, moxifloxacin AUC₀–12h/MIC exposures equivalent to those from the standard 400–mg dose were associated with good microbial kill but amplified the drug-resistant subpopulation, so that resistance emerged in 7–13 days with monotherapy (Gumbo et al., 2004). This time to emergence of resistance harmonizes well with speed of resistance emergence in patients (Ginsburg et al., 2003). Moxifloxacin exposure best associated with minimizing emergence of resistance was a non-protein bound AUC₀–₄₈h/MIC of 53. Clinical trial simulations revealed that doses greater than 400 mg a day might better achieve this AUC/MIC. Given that rifamycins reduce the moxifloxacin AUC, these results point to a potential concern of quinolone resistance.

Therapeutic Uses in Treatment of TB
Fluoroquinolones have been examined for therapeutic use in two TB contexts: for an attempt to shorten therapy duration in pulmonary TB and for the treatment of TB meningitis.

The first study was a randomized, double-blind, placebo-controlled trial that examined the effect of replacing either isoniazid or ethambutol in the standard regimen with moxifloxacin 400 mg/d for 17 weeks versus standard short-course chemotherapy (6 months) consisting of rifampin, isoniazid, ethambutol, and pyrazinamide for therapy failure or relapse (poor outcome) (Gillespie et al., 2014). While the moxifloxacin-containing regimens produced a more rapid sputum decline, there was a 6%–11% higher poor outcome compared to standard therapy. In a second randomized study, the standard short-course chemotherapy (6 months) was compared to a 4-month regimen in which isoniazid was replaced by 400 mg of gatifloxacin once a day (Merle et al., 2014). The gatifloxacin regimen was associated with greater than 2-fold higher recurrences/relapses. Thus, the quinolones failed to reduce therapy duration at the doses tested.

Fluoroquinolones have very good penetration into the CNS (Thwaites et al., 2011). A study investigating a regimen of standard therapy that included high-dose rifampin plus two different moxifloxacin regimens found that 6-month mortality was half in patients who received the high-dose rifampin intravenously and moxifloxacin (Ruslami et al., 2013). However, in a recent study of 817 patients, intensified anti-TB treatment with high-dose rifampin plus levofloxacin was not associated with a higher rate of survival among patients with tuberculous meningitis than standard treatment (Heemskerk et al., 2016).

Currently, fluoroquinolones, especially moxifloxacin, continue to be central for the treatment of pulmonary MDR-TB, and their presence or absence correlates with clinical outcomes.

Bedaquiline
Bedaquiline was discovered by Andries et al. in 2005 and entered clinical use in the treatment of TB difficult to treat with current anti-TB drugs. Bedaquiline is a cationic amphiphilic drug, which may account for its high accumulation in tissues.

Mechanism of Action
Bedaquiline acts by targeting subunit c of the ATP synthase of M. tuberculosis, leading to inhibition of the proton pump activity of the ATP synthase (Andries et al., 2005; Koul et al., 2007). Thus, the compound targets bacillary energy metabolism.

Antibacterial Activity
The bedaquiline MIC for M. tuberculosis is 0.03–0.12 mg/L. It has good activity against MAC, M. leprae, M. bovis, M. marinum, M. kansasi, M. ulcerans, M. fortuitum, M. szulgai, and M. abscessus (Andries et al., 2005; Huittic et al., 2007).

Bacterial Resistance
The proportion of M. tuberculosis mutants resistant to four times the MIC is 5 × 10⁻⁷ to 2 × 10⁻⁸. Resistance is associated with two point mutations: D32V and A63P. This region of the gene encodes the membrane-spanning domain of the ATP synthase c subunit. Recently, resistance due to efflux pump mutations and their regulators has been described.

ADME
The population PK of bedaquiline are well characterized (Swenson et al., 2016). After oral ingestion, there is a large lag time in absorption, resulting in a t₁/₂ of 5 h. The PKs are best described using a three-compartment model, with a central compartment and two peripheral compartments. The total clearance is 2.62 L/h, and the total volume of all compartments is more than 10,000 L (Swenson et al., 2016). Clearance is 52% higher in people of African descent, but 16% lower in women compared to men. The terminal t₁/₂ is about 5.5 months, mainly driven by redistribution from the tissues. Despite the extremely large volume of distribution, bedaquiline has poor CNS penetration. Bedaquiline is metabolized by CY3A4 to M2, an N-monodesmethyl metabolite.

Microbial Pharmacokinetics-Pharmacodynamics
Microbial kill of bedaquiline is believed to be linked to AUC/MIC ratios (Rouan et al., 2012). The PK-pharmacodynamic parameters linked to resistance suppression are unknown.

Efficacy and Therapeutic Use
A regimen of bedaquiline 600 mg daily for 2 weeks followed by 200 mg three times a day thereafter was added to a background second-line regimen of either kanamycin or amikacin, ofloxacin with or without ethambutol in patients with MDR-TB and led to an 8-week sputum conversion of...
about 50% with bedaquiline compared to 9% without (Diacon et al., 2009). This led to licensing of the drug, which is currently being used in combination with others for treatment of MDR-TB that is difficult to treat with other antibiotics. In a second larger study of patients with MDR-TB, at week 24, 79% of patients on bedaquiline had sputum conversion compared to 58% of those not on bedaquiline, and at 120 weeks the culture conversion rates were 62% versus 44% (Diacon et al., 2014).

**Untoward Effects**

The adverse events of bedaquiline include nausea in 26% of patients and diarrhea in 13% of patients. Other adverse effects include arthralgia, pain in extremities, and hyperuricemia and occur in a small proportion of patients (Diacon et al., 2009). The major concern with this drug is cardiovascular toxicity and death. First, there was an increased corrected QT interval of between 450 and 480 ms in 27% versus 9% on this drug compared to placebo (Kakkar and Dahlia, 2014). However, no cases of torsades de pointes have been reported. A 5-fold higher rate of death has been reported in patients on bedaquiline versus those on placebo among 160 patients. The reasons are unclear, but this has led some to question the cost-benefit effect of using this drug (Avorn, 2013). Only a limited number of patients have been exposed to this drug, so that the full side-effect profile is unclear.

**Ethionamide**

Ethionamide is a congener of thioisonicotinamide.

**Mechanism of Action**

Mycobacterial EthA, an NADPH-specific, FAD-containing monoxygenase, converts ethionamide to a sulfoxide and then to 2-ethyl-4-aminopyridine (Vannelli et al., 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Ethionamide inhibits mycobacterial growth by inhibiting the activity of the inhA gene product, the enoyl-ACP reductase of fatty acid synthase II (Larsen et al., 2002). This is the same enzyme that activatedisoniazid inhibits. Although the exact mechanisms of inhibition may differ, the results are the same: inhibition of mycolic acid biosynthesis and consequent impairment of cell wall synthesis.

**Antibacterial Activity**

The multiplication of *M. tuberculosis* is suppressed by concentrations of ethionamide ranging from 0.6 to 2.5 mg/L. A concentration of 10 mg/L or less will inhibit about 75% of photochromogenic mycobacteria; the scotochromogens are more resistant.

**Bacterial Resistance**

Resistance occurs mainly via changes in the enzyme that activates ethionamide, and mutations are encountered in a transcriptional repressor gene that controls its expression, etaR. Mutations in the inhA gene lead to resistance to both ethionamide and isoniazid.

**ADME**

The oral bioavailability of ethionamide approaches 100%. The PK are adequately explained by a one-compartment model with first-order absorption and elimination (Zhu et al., 2002) (see PK values in Table 56–2). After oral administration of 500 mg of ethionamide, a C\(_{\text{max}}\) of 1.4 mg/L is achieved in 2 h. The t\(_{1/2}\) is about 2 h. The concentrations in the blood and various organs are approximately equal. Ethionamide is cleared by hepatic metabolism. Metabolites are eliminated in the urine, with less than 1% of ethionamide excreted in an active form.

**Therapeutic Uses**

Ethionamide is administered only orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/d every 5 days until a dose of 15–20 mg/kg/d is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10–20 mg/kg/d in two divided doses, not to exceed 1 g/d.

**Untoward Effects**

Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms. Severe postural hypotension, mental depression, drowsiness, and anemia are common. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine (vitamin B\(_6\)) relieves the neurologic symptoms, and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia have also been observed. A metallic taste also may be noted. Hepatitis has been associated with the use of the ethionamide in about 5% of cases. Hepatic function should be assessed at regular intervals in patients receiving the drug.

**Para-aminosalicylic Acid**

Para-aminosalicylic acid, discovered by Lehman in 1943, was the first effective treatment of TB.

![COOH OH NH2](image)

**Mechanism of Action**

Para-aminosalicylic acid is a structural analogue of PABA, the substrate of dihydropteroate synthase (folP1/P2). As a result, PAS is thought to be a competitive inhibitor folP1, but in vitro the inhibitory activity against folP1 is very poor. However, mutation of the thymidylate synthase gene (thyA) results in resistance to PAS, but only 37% of the PAS-resistant clinical isolates or spontaneous mutants encode a mutation in the thyA gene or in any genes encoding enzymes in the folate pathway or biosynthesis of thymine nucleotides (Mathys et al., 2009). Unidentified actions of PAS likely play more important roles in its anti-TB effects.

**Antibacterial Activity**

Para-aminosalicylic acid is bacteriostatic. In vitro, most strains of *M. tuberculosis* are sensitive to a concentration of 1 mg/L. It has no activity against other bacteria.

**Bacterial Resistance**

Mutations in thyA, folC, and ribD lead to PAS resistance in up to 61% of resistant isolates (Zhang et al., 2015). Recently, MDR-TB strains due to deletions of the entire dfxA and thyA have been identified, a surprise given the conserved nature of folate synthesis (Moradigaravand et al., 2016).

**ADME**

Para-aminosalicylic acid oral bioavailability is more than 90%. PAS PK are described by a one-compartment model (Peloquin et al., 2001) (see the PK values in Table 60–2). The C\(_{\text{max}}\) increases 1.5-fold and AUC 1.7-fold with food compared to fasting (Peloquin et al., 2001). Administration with food also reduces gastric irritation. Protein binding is 50%–60%. PAS is N-acetylated in the liver to N-acetyl PAS, a potential hepatotoxic. Over 80% of the drug is excreted in the urine; more than 50% is in the form of the acetylated compound. Excretion of PAS acid is reduced by renal dysfunction; thus, the dose must be reduced in renal dysfunction.

**Therapeutic Uses**

Para-aminosalicylic acid is administered orally in a daily dose of 12 g. The drug is best administered after meals, with the daily dose divided into three equal portions. Children should receive 150–300 mg/kg/d in three or four divided doses.

**Untoward Effects**

The incidence of untoward effects associated with the use of PAS is about 10%–30%. GI problems predominate and often limit patient adherence. Hypersensitivity reactions to PAS are seen in 5%–10% of patients and manifest as skin eruptions, fever, eosinophilia, and other hematological abnormalities.
Cycloserine

Cycloserine is d-4-amino-3-isoxazolidone. It is a broad-spectrum antibiotic produced by Streptococcus orchidaceus.

Mechanism of Action
Cycloserine and d-alanine are structural analogues; thus, cycloserine inhibits alanine racemase, which converts l-alanine to d-alanine and d-alanine: d-alanine ligase, stopping reactions in which d-alanine is incorporated into bacterial cell wall synthesis.

Antibacterial Activity
Cycloserine is a broad-spectrum antibiotic. It inhibits M. tuberculosis at concentrations of 5–20 mg/L. It has good activity against MAC, enterococci, E. coli, S. aureus, Nocardia species, and Chlamydia.

Mechanisms of Resistance
Cycloserine resistance in clinical isolates of M. tuberculosis has been detected in 10%–82% of isolates (Anonymous, 2008b). Nonsynonymous SNPs and loss-of-function mutations in ald cause resistance to D-cycloserine. In addition, resistance also involves ald, the gene for alanine racemase. Nonsynonymous SNPs in ald and SNPs in the ald promoter can confer resistance to D-cycloserine (Desjardins et al., 2016).

ADME
Oral cycloserine is almost completely absorbed. The population PK are best described using a one-compartment model with first-order absorption and elimination. The drug’s t1/2 is 9 h. The Cmax in plasma is reached in 45 min in fasting subjects but is delayed for up to 3.5 h with a high-fat meal. See Table 56–2 for PK values. Cycloserine is well distributed throughout body. There is no appreciable barrier to CNS entry for cycloserine, and CSF concentrations are approximately the same as those in plasma. About 50% of cycloserine is excreted unchanged in the urine in the first 12 h; a total of 70% is recoverable in the active form over a period of 24 h. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of it is removed by hemodialysis, and the drug must be redosed after each hemodialysis session (Malone et al., 1999a).

Therapeutic Uses
Cycloserine is available for oral administration. The usual dose for adults is 250–500 mg twice daily.

Untoward Effects
Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/d, so much so that the drug has earned the nickname “psych-serine.” Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideas. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

Capreomycin
Capreomycin is an antituberculous cyclic peptide. It consists of four active components: capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Antimycobacterial activity is similar to that of aminoglycosides, as are adverse effects, and capreomycin should not be administered with other drugs that damage cranial nerve VIII. Capreomycin is a β-lactamase inhibitor. The general pharmacology of this class of compounds is discussed in Chapter 57. Recently, reports of patients with MDR-TB who have responded to β-lactam antibiotics such as ertapenem have been published (Tiberi et al., 2016). A recent meta-analysis identified seven clinical studies in which ertapenem, imipenem, and meropenem were used to treat MDR-TB and identified sputum conversion rates of greater than 60% (Sotgiu et al., 2016). The optimal doses for the treatment of MDR-TB and which antibiotics to combine are currently unknown.

β-Lactam Antibiotics for the Treatment of TB
Until recently, it was assumed that β-lactam antibiotics lacked activity against mycobacteria because the bacteria have Ambler class A β-lactamases such as BlacC. Carbapenems, which are poorer substrates of these enzymes, in conjunction with inhibitors such as clavulanate, have demonstrated efficacy against M. tuberculosis. In addition, penems such as faropenem, which possess both carbapenem and cephalosporin structures, are effective against M. tuberculosis without a β-lactamase inhibitor. The general pharmacology of this class of compounds is discussed in Chapter 57.

Macrolides
The pharmacology, bacterial activity, and resistance mechanisms of macrolides are discussed in Chapter 59. Azithromycin and clarithromycin are used for the treatment of MAC.

Dapsone
Dapsone (DDS) is a broad-spectrum agent with antibacterial, antiprotozoal, and antifungal effects.

Mechanism of Action
Dapsone is a structural analogue of PABA and a competitive inhibitor of dihydropteroate synthase (foIP1/P2) in the folate pathway, shown in the figure.
Figure 60–5. The anti-inflammatory effects of dapsone occur via inhibition of tissue damage by neutrophils (Wolf et al., 2002). Dapsone inhibits neutrophil myeloperoxidase activity and respiratory burst, and it inhibits activity of neutrophil lysosomal enzymes. Dapsone may act as a free-radical scavenger of free radicals generated by neutrophils, and dapsone may inhibit migration of neutrophils to inflammatory lesions (Wolf et al., 2002). Dapsone is extensively used for acne, but this therapy is not recommended.

Antimicrobial Effects

**Antibacterial.** Dapsone is bacteriostatic against *M. lepraes* at concentrations of 1–10 mg/L. More than 90% of clinical isolates of MAC and *M. kansasi* have an MIC of 8 mg/L or less, but the MICs for *M. tuberculosis* isolates are high. It has little activity against other bacteria.

**Antiparasitic.** Dapsone is also highly effective against *Plasmodium falciparum* with IC₅₀ of 0.6–1.3 mg/L even in sulfadoxine–pyrimethamine–resistant strains. Dapsone has an IC₅₀ of 0.55 mg/L against *Toxoplasma gondii* tachyzoites.

**Antifungal.** Dapsone is effective at concentrations of 0.1 mg/L against the fungus *Pneumocystis jiroveci*.

**Drug Resistance**

Resistance to dapsone in *P. falciparum*, *P. jiroveci*, and *M. lepraes* results primarily from mutations in genes encoding dihydropteroate synthase (Figure 60–5).

**ADME**

After oral administration, absorption is complete; the elimination tₚᵢₐᵢᵢ is 20–30 h. The population PK of dapsone is shown in Table 60–2 (Simpson et al., 2006). Dapsone undergoes N-acetylation by NAT2. N-Oxidation to dapsone hydroxylamine is via CYP2E1 and to a lesser extent by CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Epithelial lining fluid-to-plasma ratio is between 0.76 and 2.91; CSF-to-plasma ratio is 0.21–2.01 (Gatti et al., 1997). Approximately 70%–80% of a dose of dapsone is excreted in the urine as an acid-labile mono-N-glucuronide and mono-N-sulfamate.

**Therapeutic Uses**

Dapsone is administered as an oral agent. Therapeutic uses of dapsone in the treatment of leprosy are described later in this chapter. Dapsone is combined with chloroguanil for the treatment of malaria. Dapsone is also used for *P. jiroveci* infection and prophylaxis and for the prophylaxis for *T. gondii* (see Chapter 54). The anti-inflammatory effects are the basis for therapy of pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider (Wolf et al., 2002).

**Dapsone and Glucose-6-Phosphate Dehydrogenase Deficiency**

Glucose-6-phosphate dehydrogenase protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide, the most common of 100 variants being G6PD-A-. Dapsone, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of dapsone whenever possible.

**Other Untoward Effects**

Hemolysis develops in almost every individual treated with 200–300 mg of dapsone per day. Doses of 100 mg or less in healthy persons and 50 mg or less in healthy individuals with a G6PD deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes have been reported. An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally.

**Principles of Antituberculosis Chemotherapy**

**Evolution and Pharmacology**

*Mycobacterium tuberculosis* is not a single species, but a complex of species with 99.9% similarity at the nucleotide level. The complex includes *M. tuberculosis* (typus humanus), *M. canetti*, *M. africanaum*, *M. bovis*, and *M. microti*. They all cause TB, with *M. microti* responsible for only a handful of human cases.

**Antituberculosis Therapy**

Traditionally, isoniazid, pyrazinamide, rifampin, and ethambutol have been considered first-line anti-TB agents. However, the notions are shifting, with new regimens being tested with the aim of treating TB in less than 6 months, many of which are rifampin and isoniazid sparing. Moreover, antagonism between these “first-line” drugs such as isoniazid versus both rifampin and pyrazinamide has been described in murine TB models, in the hollow-fiber TB model, and in the clinic in adults and children (Chigutsa et al., 2015; Srivastava et al., 2011b; Swaminathan et al., 2016). Moxifloxacin is being studied as an agent for drug-susceptible TB, as is pretomanid and oxazolidinones. As a result, the concept of specific drugs as first line is being replaced with focus on regimens to be ranked by faster sterilizing effect. Traditionally, first-line agents were more efficacious and better tolerated relative to second-line agents. Second-line agents were used in case of poor tolerance or resistance to first-line agents. Second-line drugs included ethionamide, PAS, cycloserine, amikacin, kanamycin, and capreomycin.

The mutation rates to anti-TB drugs are between $10^{-4}$ and $10^{-6}$, so that the likelihood of resistance is high to any single anti-TB drug in patients with cavitary TB who have about $10^6$ CFU of bacillus in a 3-cm pulmonary lesion. However, the likelihood that bacilli would develop mutations to two or more different drugs is the product of two mutation rates (between $10^{-1}$ and $10^{-3}$), which makes the probability of resistance emergence to more than two drugs acceptably small. Thus, only combination anti-TB therapy is currently recommended. Multidrug therapy has led to a reduction in length of therapy.

**Types of Antituberculosis Therapy**

**Prophylaxis**

After infection with *M. tuberculosis*, about 10% of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction 5 mm or greater who also fall into one of the following categories: recently exposed to TB, have HIV coinfection, have fibrotic changes on chest radiograms, or are immunosuppressed due to HIV infection or posttransplantation or are taking immunosuppressive medications for any reason. If the tuberculin skin test is 10 mm or greater, a high risk of TB is encountered in recent (≤5 years) immigrants from areas of high TB prevalence, children younger than 4 years, children exposed to adults with TB, intravenous drug users, as well as residents and employees of high-risk congregate settings. Any person with a skin test greater than 15 mm is also at high risk of disease.

In these patients at high risk of active TB, prophylaxis is recommended to prevent active disease. Prophylaxis consists of four regimens. The shortest-duration regimen that is effective consists of isoniazid 15 mg/kg (maximum 900 mg) and weight band–based rifapentine doses administered orally once a week for 12 weeks. The weight bands for rifapentine are 300 mg for 10–14 kg, 450 mg for 14.5–25 kg, 600 mg for 25.1–32 kg, 750 mg for 32.1–49.9 kg, and 900 mg for above 50 kg. The traditional regimen consists of oral isoniazid, 300 mg daily or twice weekly, for 6 months in adults. Those who cannot take isoniazid should be given rifampin, 10 mg/kg daily, for 4 months. In children, isoniazid 10–15 mg/kg daily (maximum 300 mg) is administered, or 20–30 mg/kg two times a week directly observed, for 9 months. In children who cannot tolerate isoniazid, rifampin 10–20 mg/kg daily for 6 months is recommended.
Definitive Therapy of Drug-Susceptible TB

All active TB cases should be confirmed by culture or rapid diagnostic methods such as nucleic acid amplification tests (e.g., Xpert MTB/RIF) and have antimicrobial susceptibilities determined. In adults, the current standard regimen for drug-susceptible TB consists of isoniazid (5 mg/kg, maximum 300 mg/d), rifampin (10 mg/kg, maximum 600 mg/d), and pyrazinamide (15–30 mg/kg, maximum of 2 g/d) for 2 months, followed by intermittent 10-mg/kg rifampin and 15-mg/kg isoniazid two or three times a week for 4 months. Children should receive rifampin 10–20 mg/kg at a maximum dose of 600 mg/d, pyrazinamide 30–40 mg/kg/d, and isoniazid 10–15 mg/kg at a maximum dose of 300 mg/d. Rifabutin 5 mg/kg/d can be used for the entire 6 months of therapy in adult HIV-infected patients because rifampin can adversely interact with some antiretroviral agents to reduce their effectiveness. If there is resistance to isoniazid, initial therapy also may include ethambutol (15–20 mg/kg/d) or streptomycin (1 g/d) until isoniazid susceptibility is documented. Ethambutol doses in children are 20 mg/kg/d (maximum 1 g) or 50 mg/kg twice weekly (2.5 g).

Because monitoring of visual acuity is difficult in children younger than 5 years, caution should be exercised in using ethambutol in these children.

The first 2 months of the four-drug regimen is termed the initial phase of therapy and the last 4 months the continuation phase of therapy. Rifampentine (10 mg/kg once a week) may be substituted for rifampin in the continuation phase in patients with no evidence of HIV infection or cavitary TB. Pyridoxine, vitamin B6 (10–50 mg/d) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, HIV-infected individuals, diabetic patients, alcoholic patients, and uremic patients). To ensure compliance, therapy is administered as DOT. Although DOT is the standard of care, an analysis of a series of randomized clinical trials found no difference in outcome between DOT and self-administered therapy (Pasipanodya and Gumbo, 2013; Volmink and Garner, 2007).

The duration of therapy of drug-susceptible pulmonary TB is 6 months. A 9-month duration should be used for patients with cavitary disease who are still sputum culture positive at 2 months. HIV-infected patients with CD4+ lymphocyte cell counts less than 100/mm³ are at increased risk of developing rifampin resistance. Therefore, daily therapy is recommended during the continuation phase. Most cases of extrapulmonary TB are treated for 6 months. TB meningitis is an exception that requires a 9- to 12-month duration. In addition, results of a meta-analysis suggest that corticosteroids should be used in TB meningitis (Prasad et al., 2016).

The treatment of TB pericarditis is a special case in which the use of steroids has been advocated for many decades. In the IMPI trial that randomized 1400 patients, Mayosi and colleagues (2014) examined the effect of prednisolone on the composite outcome of death, cardiac tamponade, or coinfection. Moreover, even with the four-drug regimen of rifampin, isoniazid, ethambutol, and pyrazinamide, mortality is still very high at 26% at 6 months (and 40% in HIV-infected patients), and over several years is 1.43 per 100 person-months overall. A recent study found that free drug concentrations of rifampin in pericardial fluid were virtually close to zero, ethambutol concentrations were low, and the pH in the infected pericardial fluid was 7.34, which is the pH at which pyrazinamide has no effect (Shen et al., 2015). The optimal regimen for treatment of TB pericarditis thus remains to be identified.

Definitive Therapy of Drug-Resistant TB

The XDR-TB is MDR-TB that is also resistant to fluoroquinolones and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin). These diseases, virtually untreatable, led to the clinical trials of bedaquiline and delamanid in combination with optimized background regimens, as well as studies of linezolid. These studies demonstrated improved sputum conversion rates with these drugs. However, the adverse event rates when linezolid or bedaquiline are used are high, and it is unclear which drugs to combine with these agents to optimize efficacy and minimize adverse events rates. Thus, the exact regimens to use are still unknown. Thus, in documented drug resistance, therapy should be based on evidence of susceptibility and should include:

- at least three drugs to which the pathogen is susceptible, with at least one of the injectable anti-TB agents
- in the case of MDR-TB, a prolonged course of 5 to 7 agents, except a shorter 9-12 month regimen if there is no resistance to fluoroquinolones and second-line injectable agents (WHO, 2016).

The addition of a fluoroquinolone and surgical resection of the main lesions have been associated with improved outcome (Chan et al., 2004).

Principles of Therapy Against Mycobacterium avium Complex

The MAC is made up of at least two species: M. intracellulare and M. avium. Mycobacterium intracellulare causes pulmonary disease often in immunocompetent individuals. Mycobacterium avium is further divided into a number of subspecies: M. avium subs. hominis causes disseminated disease in immunocompromised patients, M. avium subs. paratuberculosis has been implicated in the etiology of Crohn disease, and M. avium subs. avium causes TB of birds. These bacteria are ubiquitous in the environment and can be encountered in water, food, and soil. Therefore, when MAC bacteria are isolated from a nonsterile site in a patient’s body, one cannot assume they are causing an infection.

Therapy of MAC Pulmonary Infection

Mycobacterium intracellulare often infects immunocompetent patients. Criteria in favor of therapy includes bacteriological evidence, which consists of positive cultures from at least two sputums or one positive culture from bronchoalveolar lavage or pulmonary biopsy with a positive culture or histopathological features, and clinical evidence of infection, and radiological evidence of infection such as pulmonary cavitation, nodular lesions, or bronchiectasis (Griffith et al., 2007).

In newly diagnosed patients with MAC pneumonia, triple-drug therapy is recommended. These drugs include a rifamycin, ethambutol, and a macrolide (Griffith et al., 2007; Kasperbauer and Daley, 2008). For the macrolides, either oral clarithromycin or azithromycin may be used. Rifampin is often the rifamycin of choice. Clarithromycin, 1000 mg, or azithromycin, 500 mg, are combined with ethambutol, 25 mg/kg, and rifampin, 600 mg, and administered three times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are administered for patients with cavitary disease, but the dosing regimens are azithromycin 250 mg, ethambutol 15 mg/kg, and rifabutin 600 mg. Parenteral streptomycin or amikacin at 15 mg/kg is recommended as a fourth drug. The effect of the aminoglycosides on clinical outcomes is unclear.

Duration of therapy is as for nodular disease. In advanced pulmonary disease or during re-treatment, rifabutin 300 mg daily may replace rifampin. Because clarithromycin susceptibility correlates with outcome, risk of failure is high when high clarithromycin MICs are documented. Patients at risk for failure also include those with cavitary disease, presumably due to higher bacillary load. Even with these therapies, long-term success is still fairly limited. Only half of patients have successful outcomes as defined by both culture conversion and clinical outcomes.

Therapy of Disseminated M. avium Complex

Disseminated MAC disease is caused by M. avium in 95% of patients. This is a disease of the immunocompromised patient, especially with reduced cell-mediated immunity. MAC usually occurs in patients whose CD4 cell count is less than 50/mm³. Patients at risk for infection are those who have had other opportunistic infections, are colonized with MAC, or have an HIV RNA burden greater than 5 log copies/mm³.1
The symptoms and laboratory findings of disseminated disease are nonspecific and include fever, night sweats, weight loss, elevated serum alkaline phosphates, and anemia at the time of diagnosis. However, when disease occurs in patients already on antiretroviral therapy, it may manifest as a focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection (DHHS Panel, 2008). In addition to a compatible clinical picture, isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids is required for diagnosis.

**Prophylactic Therapy**

The goals of prophylactic therapy are to prevent the development of disease during the time when a patient’s CD4 count is low. Monotherapy with either oral azithromycin 1200 mg once a week or clarithromycin 500 mg twice a day is started when patients present with a CD4 count below 50/\( \text{mm}^3 \) (DHHS Panel, 2008). For patients intolerant to macrolides, rifabutin 300 mg a day is administered. Once the CD4 count is greater than 100/\( \text{mm}^3 \) for 3 months or longer, MAC prophylaxis should be discontinued.

**Definitive and Suppressive Therapy**

In patients with disease due to MAC, the goals of therapy include suppression of symptoms and conversion to negative blood cultures. The infection itself is not completely eradicated until immune reconstitution. Therapy is divided into initial therapy and chronic suppressive therapy. Recommended therapy consists of a combination of clarithromycin 500 mg twice a day with ethambutol 15 mg/kg daily, administered orally (DHHS Panel, 2008). Azithromycin 500–600 mg daily is an acceptable alternative to clarithromycin, especially in those patients in whom clarithromycin would adversely interact with other drugs. The addition of rifabutin 300 mg/d may improve outcomes. Mortality in disseminated MAC is high in patients with either a CD4 cell count below 50/\( \text{mm}^3 \) or an MAC burden of greater than \( 2 \log_{10} \text{CFU/mm}^3 \) of blood or in the absence of effective antiretroviral therapy. In these patients, a fourth drug may be added, based on susceptibility testing. Potential fourth agents include amikacin, 10–15 mg/kg intravenously daily; streptomycin, 1 g intravenously or intramuscularly daily; ciprofloxacin, 500–750 mg orally twice daily; levofloxacin, 500 mg orally daily; or moxifloxacin, 400 mg orally daily. Patients should be continued on suppressive therapy until all three of the following criteria are met:

- therapy duration of at least 12 months
- CD4 count greater than 100/\( \text{mm}^3 \) for at least 6 months
- asymptomatic for MAC infection

**Principles of Antileprosy Therapy**

The global prevalence of leprosy has markedly declined, largely due to the global initiative of the WHO to eliminate leprosy (Hansen disease) as a public health problem by providing multidrug therapy (rifampin, clofazimine, and dapsone) free of charge. Prevalence of the disease has dropped by about 90% since 1985. Nevertheless, there are pockets of disease around the world, especially in Africa, Asia, and South America. In the U.S., fewer than 200 new cases were reported in 2005, mainly among immigrants.

Four major clinical types of leprosy affect therapy. At one end of the spectrum is *tuberculoid leprosy*, also termed paucibacillary leprosy because the bacterial burden is low and *M. leprae* is rarely found in smears. On the other end of the spectrum is the *lepromatous* form of the disease (Levis and Ernst, 2005). This is characterized by a disseminated infection and a high bacillary burden. Two major intermediate forms of the disease are recognized: (1) borderline (dimorphous) tuberculoid disease, which has features of both tuberculoid and lepromatous leprosy; and (2) indeterminate disease, which has early hypopigmented lesions without features of the lepromatous and tuberculoid leprosy.

*Mycobacterium leprae* was discovered by Armauer Hansen in 1873. The *M. leprae* genome has undergone reductive evolution and has radically downsized its genome (Cole et al., 2001). As a result, *M. leprae* cannot produce ATP from NADH or utilize acetate or galactose as carbon sources; moreover, it has lost the anaerobic electron transfer system and cannot survive under hypoxic conditions. It has a long doubling time (14 days) and is an obligate intracellular pathogen. As a result, *M. leprae* is difficult to culture on synthetic media, an impediment to basic research on the disease.

**Types of Antileprosy Therapy**

Therapy of leprosy is based on multidrug regimens using rifampin, clofazimine, and dapsone. The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. The most bactericidal drug in current regimens is rifampin. Because of high kill rates and massive release of bacterial antigens, rifampin is not often given during a “reversal” reaction (see discussion that follows) or in patients with erythema nodosum leprosum. Clofazimine is only bacteriostatic against *M. leprae*. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema nodosum leprosum. The third major agent in the regimen is dapsone. The objective of administering these drugs is total cure.

**Definitive Therapy; Standard Therapy**

**Paucibacillary Leprosy.** The WHO regimen consists of a single dose of oral rifampin, 600 mg, combined with dapsone, 100 mg, administered under direct supervision once every month for 6 months, and dapsone, 100 mg a day, in between for 6 months. In the U.S., the regimen consists of dapsone, 100 mg, and rifampin, 600 mg, daily for 6 months, followed by dapsone monotherapy for 3–5 years.

**Multibacillary Therapy.** The WHO recommends the same regimen as for paucibacillary leprosy, with two major changes. First, clofazimine, 300 mg a day, is added for the entirety of therapy. Second, the regimen lasts 1 year instead of 6 months. In the U.S., the regimen is also the same as for paucibacillary, but dual therapy continues for 3 years, followed by dapsone monotherapy for 10 years. Clofazimine is added when there is dapsone resistance or for patients who are chronically reactive.

The duration of therapy of multibacillary leprosy is a drawback. Studies in murine leprosy, and in patients, have demonstrated that viable bacilli are killed within 3 months of therapy (Ii et al., 1996), suggesting that the length of current therapy of multibacillary leprosy may be unnecessarily long. Recently, the WHO proposed that all forms of leprosy be treated with the same dose as for paucibacillary leprosy; a clinical trial was promising (Kroger et al., 2008). This new shorter regimen promises to reduce duration of therapy radically.

**Treatment of Reactions in Leprosy**

Patients with tuberculoid leprosy may develop “reversal reactions,” manifestations of delayed hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or clofazimine is effective. Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction is often associated with therapy. It is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with clofazimine or thalidomide is effective.

**Therapy of Other Nontuberculous Mycobacteria**

Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity in vitro and drug therapy selected on this basis. Therapy of infections from Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity in vitro and drug therapy selected on this basis. Therapy of infections from Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity in vitro and drug therapy selected on this basis.

| Rifampin | • Tuberculosis  
• *M. kansasii* disease  
• Leprosy  
• *M. marinum, M. ulcerans, M. malmoense, and M. haemophilum* diseases  
• Prophylaxis of meningococcal disease and *Haemophilus influenzae* meningitis  
• Brucellosis  
• Combination therapy in selected cases of staphylococcal endocarditis or osteomyelitis, especially those caused by *Staphylococcus* "tolerant" of penicillin | • Peak concentration and AUC-driven efficacy  
• Rifampin potently induces CYPs and thus increases metabolism of many classes of drugs. Prior to putting a patient on rifampin, all the patient’s medications and contraception should be examined for potential interactions.  
• Hypersensitivity reactions, especially with high-dose intermittent therapy, including flu-like symptoms, eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock  
• Hepatitis, especially in combination with other anti-TB agents, in alcoholics, or preexistent liver disease |
| Rifapentine | • Treatment of tuberculosis  
• Prophylaxis of tuberculosis | • 97% protein binding  
• Long \(t_{1/2}\) of \(\sim 14–18\) h, allowing more intermittent dosing (1–2 times weekly)  
• Moderate CYP3A induction |
| Rifabutin | • Used as rifampin replacement to avoid drug interactions of rifampin with other medications, especially in HIV coinfection  
• Treatment of disseminated MAC in patients with AIDS | • Weaker CYP3A induction than rifampin  
• Concentrations higher in tissue than plasma  
• \(t_{1/2}\) \(\sim 45\) h  
• Neutropenia in 25% of patients with HIV

Kingdom Fungi and Its Impact on Humans

There are 200,000 known species of fungi, and estimates of the total size of the kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, and smuts. About 400 fungal species cause disease in animals, and even fewer cause human disease. Nonetheless, fungal infections are associated with significant morbidity and mortality. The incidence of life-threatening fungal infections has increased in recent decades owing to an increase in immunocompromised patient populations, such as those receiving hematologic or solid-organ transplantation, cancer chemotherapy, and immunosuppressive medications, as well as those with HIV/AIDS (Richardson, 2005). This has made antifungal agents increasingly important to the practice of modern medicine. With the currently available antifungal pharmacopeia, mortality rates for invasive fungal disease remain unacceptably high (Brown et al., 2012).

Fungi are eukaryotes, making the discovery and development of drugs that target the pathogen without posing significant toxicity to the host a challenging undertaking. Differences in the biosynthesis of membrane sterols, the ability of fungi to deaminate cytosine, and the unique fungal cell wall that contains glucans and chitin all have been exploited to produce relatively safe and effective antifungal agents for the treatment of fungal infections (Roemer and Krysan, 2014). Since the advent of amphotericin B-deoxycholate in the late 1950s, research has sought safer and more effective alternatives for the treatment of systemic fungal infections. While amphotericin B remains the gold standard of systemic antifungal pharmacotherapy for a wide range of infections, alternative therapies have emerged for many clinically important fungal pathogens. This chapter provides a comprehensive overview of currently available therapeutic options for the management of invasive, mucosal, and superficial fungal infections. With only a few exceptions, the antifungals in common clinical use act mainly at sites involving the cell wall and cell membrane (Figure 61–1). Table 61–1 summarizes common fungal infections and their pharmacotherapy. Recommended adult dosages are briefly discussed for each agent. Dosing recommendations for antifungal agents in children have been recently reviewed elsewhere (Autmizguine et al., 2014).

Systemic Antifungal Agents: Drugs for Deeply Invasive Fungal Infections

Amphotericin B

Chemistry

Amphotericin B is an amphipathic or amphoteric polyene macrolide molecule with the broadest spectrum of activity of any of the currently available antifungal drugs. Polyene macrolide compounds share the characteristics of four to seven conjugated double bonds, an internal cyclic ester, poor aqueous solubility, substantial toxicity when administered systemically, and a common mechanism of antifungal action. Amphotericin B, a heptaene macrolide, contains seven conjugated trans-double bonds and a 3-amino-3,6-dideoxymannose (mycosamine) connected to the macrolide ring through a glycosidic bond (Figure 61–2). The amphoteric properties of the drug, from which it derives its name, are due to the presence of a carboxyl group on the main ring and a primary amino group on mycosamine; these groups confer aqueous solubility at extremes of pH.

Mechanism of Action

The antifungal activity of amphotericin B depends principally on its ability to bind ergosterol in the membrane of sensitive fungi. Amphotericin B has long been thought to form pores or channels that increase the permeability of the membrane and allow leakage of cytosolic molecules and ions, leading to loss of membrane integrity. However, recent evidence suggests amphotericin B forms aggregates that sequester ergosterol from lipid bilayers much like a sponge, resulting in fungal cell death (Anderson et al., 2014) (Figure 61–2).

Formulations

Four formulations of amphotericin B are commercially available: C-AMB, ABCD, L-AMB, and ABLC. Table 61–2 summarizes the pharmacokinetic properties of the available amphotericin B preparations, which have recently been extensively reviewed (see Hamill, 2013).

C-AMB. Amphotericin B is insoluble in water but, when formulated with the bile salt deoxycholate, becomes suitable for intravenous infusion. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely less than 0.4 μm in diameter. As a result, filters in intravenous infusion lines that trap particles larger than 0.22 μm in diameter will remove significant amounts of drug.
Furthermore, the addition of electrolytes to infusion solutions will cause the colloid to aggregate and complicate administration.

**ABCD.** Amphotericin B colloidal dispersion contains roughly equimolar amounts of amphotericin B and cholesterol sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when reconstituted in aqueous solution. ABCD provides much lower blood levels than C-AMB in humans. In a study of patients with neutropenic fever that compared daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common in patients who received ABCD than as compared with C-AMB (White et al., 1998). Hypoxia was associated with severe febrile reactions. In a study that compared ABCD (6 mg/kg) to C-AMB (1–1.5 mg/kg) in patients with invasive aspergillosis, ABCD was less nephrotoxic than C-AMB (15% vs. 49%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%) (Bowden et al., 2002). ABCD is currently not commercially available in the U.S.

**L-AMB.** Liposomal amphotericin B is a formulation in which AMP is incorporated within a small, unilamellar liposomal vesicle formulation. The drug is supplied as a lyophilized powder and is reconstituted with sterile water for injection (Bowtell et al., 1998). Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because L-AMB can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB (Bowtell et al., 1998) (Table 61–2).

**ABLC.** Amphotericin B lipid complex is a complex of amphotericin B with two phospholipids (dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol) (Slain, 1999). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused intravenously once daily over 2 h. Blood levels of amphotericin B are much lower with ABLC than with the same dose of C-AMB. ABLC is effective in a variety of mycoses, with the possible exception of cryptococcal meningitis. The drug is approved for salvage therapy of deep mycoses.

**Antifungal Activity**

Amphotericin B has useful clinical activity against a broad spectrum of pathogenic fungi, including Candida spp., Cryptococcus neoformans, Blastomyces dermatitidis, Histoplasma capsulatum, Sporothrix schenckii, Coccidioides spp., Paracoccidioides brasiliensis, Aspergillus spp., Penicillium marneffei, Fusarium spp., and Mucorales. Amphotericin B has limited activity against the protozoa Leishmania spp. and Naegleria fowleri. The drug has no antibacterial activity.
Fungal Resistance

Isolates of *Candida lusitaniae* are frequently resistant to amphotericin B. *Aspergillus terreus* and *Aspergillus nidulans* likewise appear to be less susceptible to amphotericin B than other *Aspergillus* species (Steinbach et al., 2004). Mutants selected in vitro for resistance to nystatin (a related polyene antifungal used topically) or amphotericin B replace ergosterol with certain precursor sterols. Mutations in ergosterol biosynthesis genes ERG2, ERG3, ERG5, ERG6, and ERG11 reduce susceptibility to amphotericin B, likely the result of reduced ergosterol in the cell membrane of these isolates (Geber et al., 1995; Hull et al., 2012; Martel et al., 2010). Resistance amongst clinical isolates of any fungal species is exceedingly rare, presumably because amphotericin B is fungicidal, and mutations that affect this critical membrane sterol are associated with significant fitness costs.

Therapeutic Uses

Typical adult doses for each amphotericin B formulation are summarized in Table 61–2. Candida esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB appears to be useful in patients with meningitis caused by *Coccidioides*. Small doses of C-AMB (from 0.01 to 1.5 mg, one to three times weekly) can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10–15 mg of hydrocortisone. However, the general use of intrathecal C-AMB administration cannot be recommended due to a lack of clinical data. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used to treat fungal endophthalmitis.

*Brunton_Ch61_p1087-p1104.indd   1089*

08/09/17 6:00 PM
The antifungal activity of amphotericin B depends on its capacity to bind ergosterol in the fungal cell membrane. Amphotericin B is an amphipathic molecule with a mycosamine moiety (shown in blue) at one end of a 14-carbon hydrophobic chain. X-ray crystallography shows the molecule to be rigid and rod shaped, with the hydrophilic hydroxyl groups of the macrolide ring forming an opposing face to the lipophilic polyene portion. B. Ergosterol, here depicted as a green rod, decorates both bilayers of the fungal membrane. C. Amphotericin B appears to form aggregates that sequester and effectively extract ergosterol from lipid bilayers, much like a selective sponge, disrupting membrane structure and resulting in fungal cell death.

Intravenous administration of amphotericin B is the treatment of choice for invasive mucormycosis and in combination with 5-flucytosine is the gold standard for induction treatment of cryptococcal meningitis. Amphotericin B is also indicated for the treatment of severe or rapidly progressive histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis. Amphotericin B is a salvage therapy for patients not responding to azole therapy for invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, or trichosporonosis. Amphotericin B (C-AMB or L-AMB) can also be given to selected patients with profound neutropenia and toxic or life-threatening fungal infections. The lipid formulations are considerably more toxic than the formulations in normal saline. They are used to minimize the side effects of amphotericin B. Adverse Effects

The major acute reactions to intravenous amphotericin B formulations are infusion-related fever and chills. These are due to the induction of a proinflammatory response in cells of the innate immune system signaling through TLR2 and CD14 (Rogers et al., 1998; Sau et al., 2003). Infusion-related reactions are most prominent with ABCD, while L-AMB administration appears to be less commonly associated with this adverse event. Tachypnea, respiratory stridor, or modest hypotension can also occur, but frank bronchospasm and anaphylaxis are rare. Patients with preexisting cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30–45 min; treatment with meperidine may shorten it.

FLUCYTOSINE

Flucytosine (5-fluorocytosine) is a fluorinated pyrimidine related to fluorouracil that has a limited role in the treatment of invasive fungal infections.

Mechanism of Action

All susceptible fungi are capable of deaminating flucytosine to 5FU (Figure 61–3), a potent antimetabolite that is used in cancer chemotherapy. Fluorouracil is metabolized first to 5FUMP by the enzyme UPRTase. 5FUMP is then either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5FUOMP, a potent inhibitor of thymidylate synthase, ultimately inhibiting DNA synthesis. The selective action of flucytosine is due to the lack of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.

ADME

Flucytosine shows excellent bioavailability on oral administration and is absorbed rapidly from the GI tract. It is widely distributed in the body, particularly to the liver and bone marrow.
with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is about 70–80 μg/mL, achieved 1–2 h after a dose of 37.5 mg/kg. The flucytosine concentration in CSF is about 65%–90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200 to 500 μg/mL. The t½ of the drug is 3–6 h in normal individuals and may be as long as 200 h in patients with renal failure. The clearance of flucytosine is approximately equivalent to that of creatinine. In patients with decreased renal function, reduction of dosage is necessary; Css should be measured periodically. Peak concentrations should range between 50 and 100 μg/mL. Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis. The drug also is removed by peritoneal dialysis.

Antifungal Activity and Fungal Resistance
Flucytosine is currently used primarily as an adjunctive agent with amphotericin B in the induction phase of cryptococcal meningoencephalitis therapy. It has in vitro activity against a number of pathogens, but the emergence of resistance limits its usefulness as single-agent therapy.

Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (Figure 61–3).

In C. albicans, substitution of thymidine for cytosine at nucleotide 301 in the gene encoding UPRTase (FUR1) causes a cysteine to become an arginine, modestly increasing flucytosine resistance (Dodgson et al., 2004). Flucytosine resistance is further increased if both FUR1 alleles in the diploid fungus are mutated.

Therapeutic Uses
Flucytosine is given orally, 50–150 mg/kg/d, in four divided doses at 6-h intervals. Dosage must be adjusted for decreased renal function. Flucytosine is used almost exclusively in combination with amphotericin B for the treatment of cryptococcal meningitis, and this combination, as compared with amphotericin B alone, is associated with improved survival amongst patients with cryptococcal meningitis (Day et al., 2013). Based on this trial, the addition of flucytosine to amphotericin B is the current gold standard for the treatment of HIV-associated cryptococcal meningitis.

In cryptococcal meningitis of non-AIDS patients, the role of flucytosine is less clear. The addition of flucytosine to 6 weeks or more of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B–induced azotemia occurs.

Adverse Effects
Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia. Patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects, including rash, nausea, vomiting, diarrhea, and severe enterocolitis, have been noted. In about 5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are concurrently receiving amphotericin B) and when plasma drug concentrations exceed 100 μg/mL. Toxicity may result from conversion of flucytosine to 5FU by the microbial flora in the intestinal tract of the host.

Imidazoles and Triazoles
The azole antifungals include two broad classes, imidazoles and triazoles. Of the drugs now on the market in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, sulconazole, tioconazole, and luliconazole are imidazoles; efinaconazole, terconazole, itraconazole, fluconazole, voriconazole, posaconazole, and isavuconazole are triazoles. The topical use of azole antifungals is described in the second section of this chapter.

Mechanism of Action
The major effect of imidazoles and triazoles on fungi is inhibition of 14-a-sterol demethylase, a CYP and the product of the gene ERG11 (Figure 61–4). Imidazoles and triazoles thus impair the biosynthesis of ergosterol, resulting in depletion of membrane ergosterol and accumulation of the toxic product 14-a-methyl-3,6-diol, leading to growth arrest (Kanafani and Perfect, 2008), possibly by disrupting the close packing of acyl chains of phospholipids and impairing the functions of membrane-bound enzyme systems. Some azoles directly increase permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

Antifungal Activity
Azoles as a group have clinically useful activity against C. albicans, Candida tropicalis, Candida parapsilosis, C. neoformans, Blastomyces dermatitidis, H. capsulatum, Coccidioides spp., Paracoccidioides brasiliensis, and ringworm fungi (dermatophytes). Aspergillus spp., Scedosporium apiospermum (Pseudallescheria boydii), Fusarium, and Sporothrix schenckii are intermediate in susceptibility. Candida glabrata exhibits reduced...
susceptibility to the azoles, whereas Candida krusei and the agents of mucormycosis are more resistant. Posaconazole and isavuconazole have modestly improved spectrum of activity in vitro against the agents of mucormycosis.

**Resistance**

In C. albicans, azole resistance can be due in part to accumulation of mutations in ERG11, the gene encoding the azole target, 14-α-sterol demethylase. Increased azole efflux by overexpression of ABC and/or major facilitator superfamily transporters impart azole resistance in C. albicans and C. glabrata. Overexpression of these genes is due to activating mutations in genes encoding their transcriptional regulators. Mutation of the C5,6 sterol desaturase gene ERG3 also can increase azole resistance in some species (Cowen et al., 2014); such mutations prevent formation of the toxic product 14α-methyl-3,6-diol from 14α-methyl-cholesterol; the resulting accumulation of 14α-methylcholesterol produces functional membranes and overcomes the effect of azoles. Increased production of 14α-sterol demethylase due to overexpression of ERG11 occurs, owing to activating mutations in the gene encoding its transcriptional regulator Upc2.

Primary azole resistance has been described in some isolates of A. fumigatus with increased azole export and decreased ergosterol content, but the clinical significance is unknown. Decreased fluconazole susceptibility has been described in C. neoformans isolated from patients with AIDS failing prolonged therapy.

**Interaction of Azole Antifungals With Other Drugs**

The azoles interact with hepatic CYPs as substrates and inhibitors (Table 61–3), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some coadministered drugs (Table 61–4). Other coadministered drugs can decrease plasma concentrations of azole antifungal agents (Table 61–5). As a consequence of these and other interactions, combinations of certain drugs with azole antifungal medications may be contraindicated (Table 61–6).

### Available Agents

**Ketoconazole.** Ketoconazole, administered orally, has been replaced by itraconazole except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Ketoconazole is available for topical use, as described further in this chapter.

**Itraconazole.** Itraconazole is a triazole that lacks the corticosteroid suppression associated with ketoconazole while retaining most of ketoconazole’s pharmacological properties and extending the antifungal spectrum. Importantly, itraconazole has activity against Aspergillus spp. while imidazoles do not. Itraconazole has been supplanted by other triazoles in the treatment of invasive mold infections but remains an important prophylactic agent in the prevention of mold infections in some patients (e.g., patients with CGD).

**ADME.** Itraconazole is available as a tablet, capsule, and a solution in hydroxypropyl-β-cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations more than 150% of those obtained with the capsule. Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. The native drug and metabolite are more than 99% bound to plasma proteins. Neither appears in urine or in CSF. The t1/2 of itraconazole at steady state is about 30–40 h. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect.

Therapeutic Uses. Itraconazole is the drug of choice for patients with indolent, nonmeningeal infections due to B. dermatitidis, H. capsulatum, P. brasiliensis, and Coccidioides immitis. The drug also is useful in the therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with amphotericin B. Approximately half of the patients with distal subungual onychomycosis respond to itraconazole (Evans and Sigurgeirsson, 1999). Although not an approved use, itraconazole is a reasonable choice for the treatment of pseudallescheriasis, an infection that does not respond to amphotericin B therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or penicilliosis have a decreased incidence of relapse if given prolonged itraconazole "maintenance" therapy. Itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term itraconazole therapy has been used in non–HIV-infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm (Salez et al., 1999).

Itraconazole solution is effective and approved for use in oropharyngeal and esophageal candidiasis. Because the solution has more GI side effects than fluconazole tablets, itraconazole solution usually is reserved for patients not responding to fluconazole. Finally, itraconazole is also used as Aspergillus prophylaxis in patients with CGD.

Dosage. In treating deep mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. Divided doses may increase the AUC. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or, for infections isolated to fingernails, two monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Once-daily terbinafine (250 mg), however, is superior to pulse therapy with itraconazole. For oropharyngeal candidiasis, itraconazole oral solution should be taken during fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect.

| TABLE 61–4 ■ DRUGS EXHIBITING ELEVATED Cₚ WHEN COADMINISTERED WITH AZOLE ANTIFUNGAL AGENTS |
|-----------------------------------------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Alfentanil                                    | Eplerenone      | Losartan        | Saquinavir      |
| Alprazolam                                    | Ergot alkaloids | Lovastatin      | Sildenafil      |
| Asenapine                                     | Ertitabine      | Methadone       | Sirolimus       |
| Buspirone                                     | Etoxicozone     | Methylprednisolone | Solifenacin |
| Busulfan                                      | Felodipine      | Midazolam       | Sunitinib       |
| Carbamazepine                                 | Fexofenadine    | Nevirapine      | Tacrolimus      |
| Cisapride                                     | Gefitinib       | Omeprazole      | Triazolam       |
| Cyclosporine                                  | Glimepiride     | Phenytoin       | Vardenafil      |
| Digoxin                                       | Glitizide       | Pimozide        | Vinca alkaloids |
| Docetaxel                                     | Halofantrine    | Quinidine       | Warfarin        |
| Dofetilide                                    | Haloperidol     | Ramelton        | Zidovudine      |
| Efavirenz                                     | Imatinib        | Ranolazine      | Zolpidem        |
| Eletriptan                                    | Irinotecan      | Risperidone     |

Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles.

| TABLE 61–5 ■ SOME DRUGS THAT DECREASE AZOLE CONCENTRATION WHEN COADMINISTERED |
|-----------------------------------------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| DRUG                                          | FLUCONAZOLE     | VORICONAZOLE    | ITRACONAZOLE    | POSACONAZOLE    | ISAVUCONAZOLE   |

| Proton pump inhibitors                        | −               | −               | +               | +               | −               |
| Phenytoin                                     | −               | +               | +               | +               |
| Rifampin                                      | +               | +               | +               | +               |
| Rifabutin                                     | +               | +               | +               | +               |
| Ritonavir                                     | +               | +               | +               | +               |

*Phenobarbital only.
*aOmeprazole and voriconazole increase each other's concentrations in plasma; reduce omeprazole dose by 50% when initiating voriconazole therapy.
*bWith standard doses of ritonavir.
Patients with esophageal thrush unresponsive or refractory to treatment with fluconazole tablets are given 100 mg of the solution twice a day for 2–4 weeks. The typical dose for fungal prophylaxis in patients with CGD is 5 mg/kg per day.

**Adverse Effects.** Serious hepatotoxicity has led, in rare cases, to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. In the absence of interacting drugs, itraconazole capsules and suspension are well tolerated at 200 mg daily. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules. Of patients receiving 50–400 mg of the capsules per day, nausea and vomiting, hypertriglyceridemia, hypokalemia, increased serum aminotransferase, and rash occurred in 2%–10%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving 600 mg or more daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses greater than 400 mg per day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome. Itraconazole is contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy.

**Drug Interactions.** Tables 61–4, 61–5, and 61–6 list select interactions of azoles with other drugs. Many of the interactions can result in serious toxicity from the companion drug, such as inducing potentially fatal cardiac arrhythmias when used with quinidine, halofantrine (an orphan drug used for malaria), levomethadyl (an orphan drug used for heroin addiction), pimozide, or cisapride (available only under an investigational limited access program in the U.S.). Other drugs may decrease itraconazole serum levels below therapeutic concentrations (Table 61–5).

**Fluconazole.** Fluconazole is a fluorinated bis-triazole.

**ADME.** Fluconazole is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4–8 μg/mL after repetitive doses of 100 mg. Renal excretion accounts for more than 90% of elimination, and the elimination half-life (t½) is 25–30 h. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50%–90% of the simultaneous values in plasma. The dosage interval should be increased from 24 to 48 h with a creatinine clearance of 21–40 mL/min and to 72 h at 10–20 mL/min. A dose of 100–200 mg should be given after hemodialysis. About 11%–12% of drug in the plasma is protein bound.

</table>
Therapeutic Uses.

- **Candidiasis.** Fluconazole, 100–200 mg daily for 7–14 days, is effective in oropharyngeal candidiasis. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A loading dose of 800 mg followed by 400 mg daily is useful in treating candidemia of nonimmunosuppressed patients (Pappas et al., 2007; Rex et al., 1994). Although response to C. glabrata bloodstream infections in randomized trials using fluconazole has been comparable to that with C. albicans, C. glabrata exhibits inherent reduced susceptibility and can become highly resistant on prolonged exposure to fluconazole. Empirical use of fluconazole for suspected candidemia may not be advisable in patients who have received long- term fluconazole prophylaxis and, as a result, may be colonized with azole-resistant C. glabrata. Based on resistance in vitro, C. krusei would not be expected to respond to fluconazole or other azoles.

- **Cryptococcosis.** Fluconazole, 400 mg daily, is used for the initial 8 weeks of the consolidation phase of the treatment of cryptococcal meningitis in patients with AIDS. Induction therapy involves an initial course of at least 2 weeks of intravenous amphotericin B. If, after 8 weeks at 400 mg per day, the patient is no longer symptomatic, then the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment of cryptococcosis, responds to HAART, has a CD4 count maintained above 200/mm³ for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. Fluconazole, 400 mg daily, has been recommended as continuation therapy in patients without AIDS with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis (Perfect et al., 2010).

- **Other Mycoses.** Fluconazole is the drug of choice for treatment of coccidiodial meningitis because of good penetration into the CSF and much less morbidity than with intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has no useful activity against histoplasmosis, blastomycosis, or sporotrichosis and is not effective in the prevention or treatment of aspergillosis. Fluconazole has no activity in mucormycosis.

**Dosage.** Fluconazole is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. The daily dose of fluconazole should be based on the infecting organism and the patient’s response to therapy. Generally, recommended dosages are 50–400 mg once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 12 mg/kg once daily (maximum 600 mg/d) without a loading dose. In adult patients, doses of up to 1200 mg have been safely administered in clinical trials for the treatment of cryptococcal meningitis.

**Adverse Effects.** Side effects in patients receiving more than 7 days of drug, regardless of dose, include headache, skin rash, vomiting, abdominal pain, and diarrhea (all at 2%–4%). Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole has been associated with skeletal and cardiac deformities in at least three infants born to two women taking high doses during pregnancy. Although a recent clinical study found no association between fluconazole receipt by mothers and most birth defects in their children, this study did find a statistically significant increase in tetralogy of Fallot in babies born to mothers who received fluconazole (Molgaard-Nielsen et al., 2013). Fluconazole should be avoided during pregnancy.

**Drug Interactions.** Fluconazole is an inhibitor of CYP3A4 and CYP2C9. Fluconazole’s drug-drug interactions are shown in Tables 61–4, 61–5, and 61–6. Patients who receive more than 400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen.

**Voriconazole.** Voriconazole is a triazole with a structure similar to fluconazole but with increased activity in vitro, an expanded spectrum, and poor aqueous solubility.

**ADME.** Voriconazole is available as 50- or 200-mg tablets or a suspension of 40 mg/mL when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat meals reduce voriconazole bioavailability, oral drug should be given either 1 h before or 1 h after meals. Oral bioavailability is 96%; volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYPs 2C19 and 2C9; CYP3A4 plays a limited role. Plasma elimination t½ is 6 h. Voriconazole exhibits nonlinear metabolism so that higher doses cause greater-than-linear increases in systemic drug exposure. Voriconazole N-oxide, a minor metabolite of voriconazole, the voriconazole N-oxide, also inhibits these polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure. About 20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Less than 2% of parent drug is recovered from urine; 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Patients with mild-to-moderate cirrhosis should receive the same loading dose of voriconazole but half the maintenance dose. The intravenous formulation of voriconazole contains SBECG, which is excrated by the kidney. Significant accumulation of SBECG occurs with a creatinine clearance less than 50 mL/min; in that setting, oral voriconazole is preferred. Therapeutic drug monitoring is frequently used, with target serum concentrations between 1 and 5 mg/L thought to maximize efficacy and minimize adverse events.

**Therapeutic Uses.** Voriconazole shows superior efficacy to C-AMB in the therapy of invasive aspergillosis using rate of response as the primary end point (Herbrecht et al., 2002); survival also is superior with voriconazole. Voriconazole was compared to L-AMB for empirical therapy of neutropenic patients whose fever did not respond to more than 96 h of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that voriconazole might be more than 10% worse than L-AMB, the FDA did not approve voriconazole for this use (Walsh et al., 2002); however, in a secondary analysis, there were fewer breakthrough infections with voriconazole (1.9%) than with L-AMB (5%). Voriconazole is approved for use in esophageal candidiasis. In nonneutropenic patients with candidemia, voriconazole is comparable in efficacy and less toxic than initial C-AMB followed by fluconazole (Kullberg et al., 2005). Voriconazole is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with P. boydii (S. apiospermum) and Fusarium infections. Positive responses in patients with cerebral fungal infections suggest that the drug penetrates infected brain.

**Dosage.** Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 h for two doses, followed by 3–4 mg/kg every 12 h, administered no faster than 3 mg/kg/h. As the patient improves, oral administration is continued as 200 mg every 12 h. Patients failing to respond may be given 300 mg every 12 h.

**Adverse Effects.** Voriconazole is teratogenic in animals and generally contraindicated in pregnancy. Although voriconazole is generally well tolerated, occasional cases of hepatotoxicity have been reported, and liver function should be monitored. Voriconazole can prolong the QTc interval, a significant issue in patients with other risk factors for torsades de pointes. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration. Symptoms diminish with time. Patients receiving their first intravenous infusion may have anaphylactoid reactions. Rash occurs in 6% of patients. The cycloextrin component of intravenous formulations may be toxic to the kidney; thus, intravenous voriconazole should be used with caution in patients with renal failure (Neofytos et al., 2012).

**Drug Interactions.** Voriconazole is metabolized by, and inhibits, CYPs 2C19, 2C9, and 3A4 (in that order of decreasing potency). The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease voriconazole plasma concentrations, respectively. Voriconazole and its major metabolite can increase the plasma concentrations of other drugs metabolized by these enzymes (Tables 61–4, 61–5, and 61–6). Because the
AUC of sirolimus increases 11-fold in the presence of voriconazole, coadministration is contraindicated. When starting voriconazole in a patient receiving 40 mg/d or more of omeprazole, the dose of omeprazole should be reduced by half.

**Posaconazole.** Posaconazole is a synthetic structural analogue of itraconazole with the same broad antifungal spectrum but with up to 4-fold greater activity in vitro against yeasts and filamentous fungi, including some, but not all, of the agents that cause mucormycosis (Frampton and Scott, 2008). Activity against yeasts in vitro is similar to voriconazole. The mechanism of action is the same as other imidazoles, inhibition of sterol 14α-demethylease.

**ADME.** Posaconazole is available as a flavored suspension containing 40 mg/mL. Bioavailability of the oral suspension is significantly enhanced by the presence of food (Courtney et al., 2003; Krieter et al., 2004). The drug has a long t1/2 (25–31 h), a large volume of distribution (331–1341 L), and extensive protein binding (>98%). Systemic exposure is four times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7–10 days when dosed four times daily. Renal impairment does not alter plasma concentrations; hepatic impairment causes a modest increase. Almost 80% of the drug is excreted in the stool, with 66% as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation (Krieter et al., 2004). Hemodialysis does not remove drug from the circulation. Gastric acid improves absorption (Krishna et al., 2009); drugs that reduce gastric acid (e.g., cimetidine and esomeprazole) decrease posaconazole exposure by 32%–50% (Frampton and Scott, 2008). Diarrhea reduces the average C3 by 37% (Smith et al., 2009). The delayed-release tablet and intravenous formulations provide a more consistent bioavailability in the presence of concomitant disease states, medications, and dietary considerations that alter concentrations achievable with the oral suspension (Guarascio and Slain, 2015).

**Therapeutic Uses.** Posaconazole is approved for treatment of oropharyngeal candidiasis, although fluconazole is the preferred drug because of safety and cost. Posaconazole is also approved for prophylaxis against candidiasis and aspergillosis in patients more than 13 years of age who have prolonged neutropenia or severe GVHD (Ullmann et al., 2007). It is approved in the E.U. as salvage therapy for aspergillosis and several other infections, as are itraconazole and voriconazole.

**Dosage.** For prophylaxis of invasive Aspergillus and Candida infections, the adult intravenous dose is 300 mg twice on day 1 and 300 mg daily thereafter. Duration of therapy is based on recovery from neutropenia or immunosuppression. The same dose is used for the delayed-release tablets. The dose for the oral suspension is 200 mg (5 mL) three times daily.

**Adverse Effects.** Common adverse effects include nausea, vomiting, diarrhea, abdominal pain, and headache (Smith et al., 2009). Although adverse effects occur in at least a third of patients, the rate of discontinuation due to adverse effects in long-term studies has been only 8%.

**Drug Interactions.** Posaconazole inhibits CYP3A4. Coadministration with rifabutin or phenytoin increases the plasma concentration of these drugs and decreases posaconazole exposure by 2-fold. Posaconazole increases the AUC of cyclosporine, tacrolimus (121%), sirolimus (790%), midazolam (83%), and other CYP3A4 substrates (Table 61–4) (Frampton and Scott; 2008; Krishna et al., 2009; Moton et al., 2009). Posaconazole can prolong the QTc interval and should not be coadministered with drugs that are CYP3A4 substrates that likewise prolong the QTc interval, such as methadone, haloperidol, pimozide, quinidine, risperidone, sunitinib, tacrolimus, and halofantrine (Table 61–4).

**Isavuconazole.** Isavuconazole is a triazole that is administered as the isavuconazonium prodrug.

**ADME.** Isavuconazole is available in both oral and cyclodextrin-free intravenous formulations. It is highly bioavailable (98%) and is more than 99% protein bound in serum. Administration of oral isavuconazonium with food reduces AUC by about 20%. Isavuconazole is eliminated by hepatic metabolism, predominantly by CYP3A4 and CYP3A5. Less than 1% of isavuconazole is excreted unchanged in urine. No renal dose adjustments are needed (Rybak et al., 2015).

**Therapeutic Uses.** Isavuconazole exhibits a broad spectrum of activity against most yeast species, including Candida species, Cryptococcus gattii and C. neoformans, and molds such as Aspergillus species and Mucoarales species complex. The drug is approved for the treatment of invasive aspergillosis and invasive mucormycosis and is under investigation for treatment of candidemia and invasive candidiasis.

**Dosage.** Isavuconazole is dosed as 372 mg isavuconazonium sulfate (equivalent to 200 mg of isavuconazole) every 8 h for six doses followed by 372 mg isavuconazonium sulfate by mouth or intravenously once daily starting 12 to 24 h after the last loading dose.

**Adverse Effects.** Isavuconazole is generally well tolerated. GI disorders, pyrexia, hypokalemia, headache, constipation, and cough are the most frequently reported adverse effects.

**Drug Interactions.** Isavuconazole is both a substrate and an inhibitor of CYP3A4. Consequently, a 5-fold increase in isavuconazole AUC results when it is administered with strong CYP inhibitors such as ketoconazole. Substantial reductions in isavuconazole AUC also result from coadministration of isavuconazole with rifampin. Midazolam and sirolimus AUCs are increased by coadministration with isavuconazole. Importantly, isavuconazole does not appear to prolong QTc.

**Echinocandins**

Echinocandins are cyclic lipopeptides with a hexadepsipeptide nucleus. Three echinocandins are approved for clinical use: caspofungin, anidulafungin, and micafungin. All act through the same mechanism but differ in pharmacological properties. Fungi that are susceptible to echinocandins include Candida and Aspergillus spp. (Bennett, 2006).

**General Pharmacological Characteristics**

**Mechanism of Action.** The echinocandins inhibit 1,3-β-D-glucan synthesis, which is an essential component of the fungal cell wall and is required for cellular integrity (Figure 61–5).

**Antifungal Activity.** Echinocandins exhibit fungicidal activity against Candida species. In contrast, they are fungistatic against Aspergillus species and cause morphological changes to the filaments. Echinocandins do not appear to have clinically useful activity against dimorphic fungi such as H. capsulatum and have no activity against C. neoformans, Trichosporon spp., Fusarium spp., or agents of mucormycosis.

**Resistance.** Echinocandin resistance has emerged as a clinical problem and results from mutations leading to amino acid substitutions in the Fks subunits of glucan synthase (Cowan et al., 2014). Multidrug transporters do not appear to play a role in echinocandin resistance. Mutations conferring resistance occur in two conserved “hot spot” regions of FKS1 in C. albicans and in FKSI and FK52 in C. glabrata. Candida parapsilosis complex and Candida guilliermondii display reduced in vitro echinocandin susceptibility as compared to other Candida species owing to inherently occurring polymorphisms in Fks hot spot regions. Species-specific clinical breakpoints for echinocandins have been recently described.

Echinocandins differ somewhat pharmacokinetically (Table 61–7) but all share extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight-to-moderate effect of hepatic insufficiency on plasma drug concentrations (Kim et al., 2007; Wagner et al., 2006). Currently available echinocandins also lack oral bioavailability and are available only for intravenous administration. Generally speaking, adverse effects are minimal and rarely lead to drug discontinuation (Kim et al., 2007). All three agents are well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. All three echinocandins are contraindicated in pregnancy.

**Available Agents**

**Caspofungin.** Caspofungin acetate is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of Glarea lozoyensis (Johnson and Perfect, 2003; Keating and Figgitt, 2003).
Chemotherapy of Infectious Diseases

Section VII

ADME
Catabolism is largely by hydrolysis and N-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increase the AUC by 55% and 76%, respectively.

Therapeutic Use
Caspofungin is approved for the treatment of invasive candidiasis and as salvage therapy for patients with invasive aspergillosis who fail or are intolerant of approved drugs, such as amphotericin B formulations or voriconazole. Caspofungin is also approved for both esophageal and invasive candidiasis (Mora-Duarte et al., 2002; Villanueva et al., 2001) and for treatment of persistently febrile neutropenic patients with suspected fungal infections (Walsh et al., 2004).

Dosage
Caspofungin is administered intravenously once daily over 1 h. For candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving rifampin as well as in those failing to respond to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

Drug Interactions
Caspofungin increases tacrolimus levels by 16%, which should be managed by standard monitoring. Cyclosporine slightly increases caspofungin levels. Rifampin and other drugs activating CYP3A4 can cause a slight reduction in caspofungin levels.

Micafungin
Micafungin has linear pharmacokinetics over a large range of doses (1–3 mg/kg) and ages (premature infants to elderly). Small amounts of drug are metabolized in the liver by arylsulfatase and catechol O-methyltransferase. Hydroxylation by CYP3A4 is barely detectable. Unlike caspofungin, reduction of the micafungin dose in moderate hepatic failure is not required. Micafungin shows age-dependent clearance in children, with rapid clearance in premature infants and intermediate clearance in children 2–8 years of age, compared to older children and adults.

In normal volunteers, micafungin appears to be a mild inhibitor of CYP3A4, increasing the AUC of nifedipine by 18% and sirolimus by 21%. Micafungin has no effect on tacrolimus clearance.

Therapeutic Uses
Micafungin is approved for the treatment of invasive candidiasis (Fritz et al., 2008) and esophageal candidiasis and for prophylaxis in hematopoietic stem cell transplant recipients.

Dosage
Micafungin is administered intravenously as a 100-mg daily dose over 1 h for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis. No loading dose is required.

Anidulafungin
Anidulafungin is a water-insoluble semisynthetic compound extracted from the fungus A. nidulans, from which the drug’s name derives.

ADME
Anidulafungin is cleared from the body by slow chemical degradation (Vazquez and Sobel, 2006). No hepatic metabolism or renal excretion of active drug occurs; thus, no dose adjustment for hepatic or renal failure is needed. No clinically relevant drug-drug

interactions have been observed with drugs likely to be coadministered with anidulafungin.

**Therapeutic Use and Dosing.** Anidulafungin is approved for the treat-
mend of candidemia and other forms of *Candida* infections (Reboli et al.,
2007), including intra-abdominal abscess, peritonitis, and esophageal can-
didiasis. For invasive candidiasis, anidulafungin is given daily as a loading
dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading
dose of 100 mg is followed by 50 mg daily.

### Other Systemic Antifungal Agents

**Griseofulvin.** Griseofulvin is an orally administered, fungistatic antifun-
gal agent originally isolated from the mold *Penicillium griseofulvum*. It is
practically insoluble in water.

**Mechanism of Action.** Griseofulvin inhibits microtubule function and
thereby disrupts assembly of the mitotic spindle, which disrupts fungal
cell division.

**ADME.** Blood levels after oral administration of griseofulvin are quite
variable. Some studies have shown improved absorption when the drug is
taken with a fatty meal. Because the rates of dissolution and disaggrega-
tion limit the bioavailability of griseofulvin, microsize and ultramicrosize
powders are now used. Griseofulvin has a plasma *t*1/2 of about 1 day; about
50% of the oral dose can be detected in the urine within 5 days, mostly
in the form of metabolites. The primary metabolite is methylgriseofulvin.
Barbiturates decrease griseofulvin absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells dif-
f erentiate, the drug is tightly bound to, and persists in, keratin, providing
prolonged resistance to fungal invasion. For this reason, the new growth of
hair or nails is the first to become free of disease. As the fungus-containing
keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable
in the stratum corneum of the skin within 4–8 h of oral administration.
Sweat and transepidermal fluid loss play an important role in the transfer
of the drug in the stratum corneum. Only a very small fraction of a dose
of the drug is present in body fluids and tissues.

**Antifungal Activity.** Griseofulvin is fungistatic in vitro for various spe-
cies of the dermatophytes *Microsporum*, *Epidermophyton*, and *Trichophy-
ton*. The drug has no effect on other fungi or on bacteria. Although failure
of ringworm lesions to improve is not rare, isolates from these patients
usually are still susceptible to griseofulvin in vitro.

**Therapeutic Uses.** Mycotic disease of the skin, hair, and nails due to
*Microsporum*, *Trichophyton*, or *Epidermophyton* responds to griseofulvin
therapy. For tinea capitis in children, griseofulvin remains the drug of
choice for efficacy, safety, and availability as an oral suspension. Efficacy
is best for tinea capitis caused by *Microsporum canis*, *Microsporum audou-
ini*, *Trichophyton schoenleinii*, and *Trichophyton verrucosum*. Griseofulvin
is also effective for ringworm of the glabrous skin; tinea cruris and tinea
corporis caused by *M. canis*, *Trichophyton rubrum*, *T. verrucosum*, and
*Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *Tri-
chophyton mentagrophytes*) and beard (*Trichophyton species*). Griseoful-
vin also is highly effective in the treatment of tinea pedis, the vesicular
form of which is most commonly due to *T. mentagrophytes* and the hyper-
keratotic type to *T. rubrum*. Topical therapy is sufficient for most cases of
tinea pedis. *Trichophyton rubrum* and *T. mentagrophytes* infections may
require higher-than-conventional doses of griseofulvin. Treatment must
be continued until infected tissue is replaced by normal hair, skin, or nails,
which requires 1 month for scalp and hair ringworm, 6–9 months for
fingernails, and at least a year for toenails. Itraconazole or terbinafine
is much more effective for onychomycosis.

**Adverse Effects.** The incidence of serious reactions due to griseofulvin
is very low: headache (15% of patients), GI and nervous system manifes-
tations, and augmentation of the effects of alcohol. Hepatotoxicity has
been observed. Hematological effects include leukopenia, neutropenia,
punctate basophilia, and monocytosis; these often disappear despite con-
tinued therapy. Blood studies should be carried out at least once a week
during the first month of treatment or longer. Common renal effects include
albuminuria and cylindruria without evidence of renal insufficiency.
Reactions involving the skin are cold and warm urticaria, photosensitivity,
lichen planus, erythema, erythema multiforme–like rashes, and vesicu-
lar and morbilliform eruptions. Serum sickness syndromes and severe
angioedema develop rarely. Estrogen-like effects have been observed in
children. A moderate but inconsistent increase of fecal protoporphyrins
has been noted with chronic use.

**Drug Interactions.** Griseofulvin induces hepatic CYPs and thereby
increases the rate of metabolism of warfarin. Consequently, the dose of
warfarin should be adjusted in some patients. The drug may also reduce
the efficacy of low-estrogen oral contraceptive agents, probably by a
similar mechanism.

**Terbinafine.** Terbinafine is well absorbed, but bioavailability is about 40%
due to first-pass metabolism in the liver. The drug accumulates in skin,
nails, and fat. The initial *t*1/2 is about 12 h but extends to 200–400 h at
steady state. Terbinafine is not recommended in patients with marked
azotemia or hepatic failure. Rifampin decreases and cimetidine increases
plasma terbinafine concentrations.

**Therapeutic Uses.** Terbinafine, given as one 250-mg tablet daily for
adults, is somewhat more effective than itraconazole for nail onychomyc-
cosis. Duration of treatment varies with the site of infection but typically
ranges between 6 and 12 weeks. The efficacy for the treatment of ony-
chomycosis can be improved by the simultaneous use of amorolfine 5%
nail lacquer (amorolfine is not approved for use in the U.S.). Terbinafine
is also effective for the treatment of tinea capitis and has been used for the
off-label treatment of ringworm elsewhere on the body.

**Adverse Effects.** The drug is well tolerated, with a low incidence of GI
distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neu-
ropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may
occur. Systemic terbinafine therapy for onychomycosis should be postponed
until after pregnancy is complete.

### Agents Active Against Microsporidia and Pneumocystis

**Microsporidia** are spor-forming unicellular eukaryotic organisms that
were once thought to be parasites but are now classified as fungi (Field
and Milner, 2015). They can cause several disease syndromes, including
diarrhea in immunocompromised individuals.

**Albendazole**

Intestinal infections with most microsporidia are treated with albend-
azole, an inhibitor of α-tubulin polymerization (see Chemotherapy of
Helminth Infections, Chapter 55) (Anane and Attouchi, 2010).

**Fumagillin**

Fumagillin is an acrylic polyene macrolide produced by the fungus *A.
flumigatus*. Fumagillin and its synthetic analogue TNP-470 are toxic to
microsporidia. Immuno compromised individuals with intestinal microsporidiosis
due to *Enterocytozoon bieneusi* (which does not respond as well to albend-
azole) can be treated successfully with fumagillin (Didier et al., 2005; Rex
and Stevens, 2014; Szumowski and Troemel, 2015). For the treatment of
intestinal microsporidiosis caused by *E. bieneusi*, fumagillin is used at a
dose of 20 mg orally three times daily for 2 weeks (Medical-Letter, 2013;
Molina et al., 2002; Rex and Stevens, 2014). Fumagillin is used topically
to treat keratoconjunctivitis caused by *Encephalitozoon hellem* at a dose of
3–10 mg/mL in a balanced salt suspension. Adverse effects of fumagillin
may include abdominal cramps, nausea, vomiting, and diarrhea. Revers-
ible thrombocytopenia and neutropenia also have been reported (Anane
and Attouchi, 2010). Fumagillin is not approved for use in humans in
the U.S.

**Pentamidine**

*Pneumocystis jiroveci* is another fungus that, until recently, was clas-
sified as a protozoan parasite. It is the causative agent of PJP, formerly
known as PCP. Pentamidine is one of several drugs or drug combina-
tions used to treat or prevent PJP, which is a major cause of mortality in

---

*Brunton_Ch61_p1087-p1104.indd* 1098

08/09/17 6:00 PM
immunocompromised individuals, including patients with AIDS. Note, however, that _trimethoprim-sulfamethoxazole_ is the drug of choice for the treatment and prevention of PJP (see Chapter 56).

**Therapy for PJP.** Pentamidine as therapy for PJP is reserved for two indications:

- as a 4 mg/kg single daily intravenous dose for 21 days to treat severe PJP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agent; and
- as a “salvage” agent for individuals with PJP who fail to respond to trimethoprim-sulfamethoxazole (pentamidine may be less effective than the combination of clindamycin and primaquine or atovaquone for this indication) (Gilroy and Bennett, 2011; Rex and Stevens, 2014).

**Prophylaxis.** Pentamidine administered as an aerosol preparation is used to prevent PJP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole, as patients with severe bone marrow suppression. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5%–10% nebulized solution over 30–45 min (Gilroy and Bennett, 2011). Aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of _Pneumocystis_, the lack of efficacy against any other potential opportunistic pathogens, and a risk for pneumothorax (Rex and Stevens, 2014).

**Topical Antifungal Agents**

Topical agents are useful for the treatment of many superficial fungal infections, such as those confined to the stratum corneum, squamous mucosa, or cornea. Examples of infections that respond to topical therapy include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Preferred formulations for cutaneous application usually are creams or solutions. Ointments are inconvenient and can be too occlusive to the skin, particularly if the affected area is a macerated, fissured, or intertriginous lesion. Antifungal powders, whether applied by shake containers or aerosols, are useful only for lesions of the feet, groin, and similar intertriginous areas. With few exceptions, topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and should not be used for the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy.

**Topical Imidazoles and Triazoles**

The imidazoles and triazoles are closely related classes of drugs that are synthetic antifungal agents used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is rare amongst the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability because in vitro fungal susceptibility testing does not correlate with clinical responses. The mechanism of action of the azole antifungals was discussed previously in this chapter.

**Modes of Administration**

**Cutaneous Application.** The preparations for cutaneous use described in the following material are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3–6 weeks. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

**Vaginal Application.** Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1–7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher dose of each. These preparations are administered for 3–7 days. Approximately 3%–10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience mild penile irritation.

**Oral Use.** Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

**Individual Agents**

**Clotrimazole**

Absorption of clotrimazole is less than 0.5% after application to the intact skin; from the vagina, it is 3%–10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. In adults, an oral dose of 200 mg/d will give rise initially to plasma concentrations of 0.2–0.35 μg/mL, followed by a progressive decline. In a small fraction of patients, clotrimazole on the skin may cause skin irritation, stinging sensations, erythema, edema, vescication, desquamation, pruritus, or urticaria. When applied to the vagina, about 1.6% of patients experience a mild burning sensation. In rare instances, lower abdominal cramps, a slight increase in urinary frequency, or skin rash may occur. Occasionally, a patient’s sexual partner may experience penile or urethral irritation. Oral clotrimazole troches cause GI irritation in about 5% of patients.

**Therapeutic Uses.** Clotrimazole is available as a 1% cream, lotion, powder, aerosol solution, and solution; 1% or 2% vaginal cream; vaginal tablets of 100, 200, or 500 mg; and 10-mg troches. On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth five times a day for 14 days. Topical clotrimazole cures dermatophyte infections in 60–100% of cases. The cure rates in cutaneous candidiasis are 80%–100%. In vulvovaginal candidiasis, the cure rate is usually greater than 80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

**Econazole**

Econazole is the deschloro- derivative of miconazole. Econazole readily penetrates the stratum corneum and achieves effective concentrations at the level of the middermis. Approximately 3% of recipients experience local erythema, burning, stinging, or itching. Econazole nitrate is available as a water-miscible cream (1%) to be applied twice a day.

**Efinaconazole**

Efinaconazole is an azoleamine derivative with excellent in vitro activity against _T. rubrum_ and _T. mentagrophytes_. It is available as a 10% topical solution for the treatment of onychomycosis.

**Miconazole**

Miconazole readily penetrates the stratum corneum of the skin and persists for more than 4 days after application. Adverse effects from topical application to the vagina include burning, itching, or irritation in about 7% of recipients, as well as infrequent pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy, although some experts advocate avoiding vaginal use during the first trimester.

**Therapeutic Uses.** Miconazole nitrate is available as a 2% cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution. To avoid
Ciclopirox
During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and “sensitization” and species of Haloprogin is a halogenated phenolic ether. It is fungicidal to various treatment of mild-to-moderate superficial white onychomycosis. No topical toxicity has been noted. Cure rates in the dermatomycoses and candidal infections are 81%–94%. Tetrates hair follicles and sebaceous glands. It can sometimes cause hyperetrates the epidermis to reach the dermis, but even under occlusion, appears to chelate trivalent metal cations and thereby inhibits metal-
Ciclopirox olamine has broad-spectrum antifungal activity. It is fungicidal to C. albicans, E. floccosum, M. canis, T. mentagrophytes, and T. rubrum. It also inhibits the growth of Malassezia furfur. Ciclopirox appears to chelate trivalent metal cations and thereby inhibits metal-dependent enzymes required for degradation of peroxides within the fungal cell (Subissi et al., 2010). After application to the skin, it penetrates the epidermis to reach the dermis, but even under occlusion, less than 1.5% is absorbed into the systemic circulation. Furthermore, because the $t_{1/2}$ is 1.7 h, no systemic accumulation occurs. The drug penetrates hair follicles and sebaceous glands. It can sometimes cause hyper sensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% nail lacquer is available for onychomycosis. Cure rates in the dermatomycoses and candidal infections are 81%–94%. No topical toxicity has been noted.
Ciclopirox 0.77% gel and 1% shampoo are also used for the treatment of seborrheic dermatitis of the scalp. An 8% topical solution is an effective treatment of mild-to-moderate superficial white onychomycosis.

HALOPROGIN
Haloprogin is a halogenated phenolic ether. It is fungicidal to various species of Epidermophytum, Pityrosporum, Microsporum, Trichophyton, and Candida. During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and “sensitization” (or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive footgear is worn. Haloprogin is poorly absorbed through the skin; it is metabolized to trichlorophenol in the patient. However, systemic toxicity from topical application appears to be low. Haloprogin cream or solution is applied twice a day for 2–4 weeks. Its principal use is against tinea pedis, for which the cure rate is about 80%; it is thus approximately equal in efficacy to tolnaftate. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the U.S.

TOLNAFTATE
Tolnaftate is a thiocarbamate that is effective in the treatment of most cutaneous mycoses caused by T. rubrum, T. mentagrophytes, Trichophyton tonsurans, E. floccosum, M. canis, M. audouini, Microsporum gypseum, and M. furfur, but it is ineffective against Candida. In tinea pedis, the cure rate is about 80%, compared with about 95% for miconazole. Tolnaftate is available in a 1% concentration as a cream, gel, powder, aerosol powder, topical solution, or a topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is usually relieved in 24–72 h. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7–21 days. Toxic or allergic reactions to tolnaftate have not been reported.

NAFTINE
Naftifine is a synthetic allylamine that inhibits squalene-2,3-epoxidase, a key enzyme in the fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity in vitro. Naftifine hydrochloride is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Allergic contact dermatitis also has been reported. Naftifine also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

TERBINAFINE
Like naftifine, terbinafine is an allylamine that targets ergosterol biosynthesis. Terbinafine 1% cream or spray, applied twice daily, is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against Candida species and Malassezia furfur, but the cream also can be used in cutaneous candidiasis and tinea versicolor.

BUTENAFINE
Butenafine hydrochloride is a benzylamine derivative with a mechanism of action similar to that of terbinafine and naftifine. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

TAVABOROLE
Tavaborole is an oxaborole antifungal indicated for the topical treatment of onychomycosis of the toenails. The drug inhibits fungal leucyl-tRNA synthetase, thereby inhibiting protein synthesis and ultimately causing fungal cell death.

NYSTATIN
Nystatin, a tetraene macrolide produced by Streptomyces noursei, is structurally similar to amphotericin B and acts through the same mechanism of action. The drug is not absorbed from the GI tract, skin, or vagina. Nystatin is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions such as diaper rash and are applied two to three times daily. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available.

Allergic reactions to nystatin are uncommon. Although vaginal tablets of nystatin are well tolerated, imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis. Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host and is widely used in neonates and infants for oral thrush. Patients should be instructed to swish the drug around in the mouth and then swallow; otherwise, the patient may expectorate the bitter liquid and
fail to treat the infected mucosa in the posterior pharynx or esophagus. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

**Undecylenic Acid**

Undecylenic acid is 10-undecenoic acid, an 11-carbon unsaturated compound. It is primarily fungistatic, although fungicidal activity may be observed with long exposure to high concentrations of the agent. The drug is active against a variety of fungi, including those that cause ringworm. Undecylenic acid is available in a cream, powder, spray powder, soap, and liquid. Zinc undecylenate is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compounded undecylenic acid ointment contains both undecylenic acid (~5%) and zinc undecylenate (~20%). Calcium undecylenate is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compounded ointment, may be applied to the skin. These preparations are usually not irritating to tissue, and sensitization to them is uncommon. This agent retards fungal growth in tinea pedis, but the infection frequently persists despite intensive treatment with preparations of the acid and the zinc salt. At best, the clinical “cure” rate is about 50%, which is much lower than that obtained with the imidazoles, haloprogin, or tolnaftate. Efficacy in the treatment of tinea capitis is marginal, and the drug is no longer used for that purpose. Undecylenic acid preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

**Benzoic and Salicylic Acids**

An ointment containing benzoic and salicylic acids in a ratio of 2:1 (usually 6% and 3%) is known as Whitfield ointment. It combines the fungistatic action of benzoate with the keratolytic action of salicylate and is used mainly in the treatment of tinea pedis. Because benzoic acid is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed; thus, continuous medication is required for several weeks to months. The salicylic acid accelerates desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.

# Antifungal Agents

## Chapter 61

### Imidazoles and Triazoles: Inhibit ergosterol biosynthesis

**Fluconazole**
- Invasive candidiasis
- Cryptococcosis
- Coccioidiomycosis
- Prophylaxis and empirical therapy in immunocompromised host
- Plasma concentrations are essentially the same whether the drug is given orally or intravenously.
- Concentrations in CSF = 50%–90% of C\text{p}
- Inhibitor of CYP3A4 and CYP2C9
- Contraindicated during pregnancy

**Voriconazole**
- Invasive aspergillosis
- Invasive candidiasis
- Pseudallescheriasis
- Oral bioavailability is 96%.
- Monitor C\text{p}; serum levels of 1 to 5 mg/L maximize efficacy and minimize toxicity
- Inhibits CYP3A4 and CYP2C9
- Can prolong the QTc interval
- Transient visual or auditory hallucinations are frequent after the first dose.
- Contraindicated in pregnancy

**Posaconazole**
- Oropharyngeal candidiasis
- Prophylaxis in the immunocompromised host against aspergillosis and candidiasis
- Oral bioavailability enhanced by food
- Drugs that ↓ gastric acid ↓ posaconazole exposure
- Inhibits CYP3A4
- Can prolong the QTc interval
- Adverse effects: headache and GI disorders

**Isavuconazole** (isavuconazonium prodrug)
- Invasive aspergillosis
- mucormycosis
- Oral bioavailability is 98%.
- Substrate of and inhibitor of CYP3A4
- Does not appear to prolong QTc

### Echinocandins: Inhibit 1,3-β-D-glucan synthesis in the fungal cell wall

**Caspofungin**
- Invasive candidiasis
- Empirical therapy in the immunocompromised host
- ↓ Dose in moderate hepatic impairment

**Micafungin**
- Invasive candidiasis
- Prophylaxis in the immunocompromised host
- Reduction of micafungin dose in moderate hepatic failure is not required.

**Anidulafungin**
- Invasive candidiasis
- No dose adjustment is needed for hepatic or renal failure.

### Griseofulvin: Inhibits microtubule function, disrupts assembly of the mitotic spindle

**Griseofulvin**
- Ringworm
- Onychomycosis
- Absorption is reduced by barbiturates
- Induces hepatic CYPs

### Allylamines: Inhibit fungal squalene epoxidase and reduce ergosterol biosynthesis

**Terbinafine**
- Ringworm
- Onychomycosis
- Bioavailability is ~ 40% due to first-pass metabolism in the liver.
- The drug accumulates in skin, nails, and fat.
- The initial t\text{1/2} is ~ 12 h but extends to 200–400 h at steady state.

### Agents Active Against Microsporidia and Pneumocystis

**Albendazole**
- Microsporidia infection
- Anthelmintic
- Inhibitor of α-tubulin polymerization

**Fumagillin**
- Microsporidia infection
- Used in immunocompromised individuals with intestinal microsporidiosis due to Enterocytozoon bieneusi unresponsive to albendazole
- Not approved for human use in the U.S.

**Trimethoprim-sulfamethoxazole**
- Pneumocystis jiroveci pneumonia
- See Chapter 56

**Pentamidine**
- Pneumocystis jiroveci pneumonia
- Prophylaxis use to prevent PJP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole

### Topical Antifungal Agents

**Imidazoles and Triazoles**
- Clotrimazole, miconazole, ketoconazole, etc.
- Dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis
- Available for cutaneous application as creams or solutions
- Some are available as vaginal creams or suppositories or as oral troches

**Tavaborole**
- Toenail onychomycosis due to T. rubrum or T. mentagrophytes
- Apply daily for 48 weeks

VIRAL REPLICATION AND DRUG TARGETS

ANTIPRONIVIRUS AGENTS
- Acyclovir and Valacyclovir
- Cidofovir
- Famciclovir and Penciclovir
- Ganciclovir and Valganciclovir
- Foscarnet
- Fomiviren
- Docosanol

ANTI-INFLUENZA AGENTS
- Amantadine and Rimantadine
- Oseltamivir
- Zanamivir
- Peramivir
- Interferon

Chapter 62

Antiviral Agents (Nonretroviral)
Edward P. Acosta

Most antivirals currently available in the U.S. have been developed and approved in the last 25 years. This flurry of activity was driven by successes in rational drug design and approval that began with the antiviral nucleoside analogue acyclovir (Elion, 1986), whose discovery and development resulted in the awarding of a Nobel Prize to Gertrude Elion and George Hitchings in 1988. Because viruses are obligatory intracellular microorganisms and rely on host biosynthetic machinery to reproduce, there were doubts about the possibility of developing antiviral drugs with selective toxicity, but those doubts have long been erased. Viruses are now obvious targets for effective antimicrobial chemotherapy, and it is certain that the number of available agents in this category will continue to increase. Indeed, the recent development of agents that target the viral protein NS5A has revolutionized treatment of infections of HVB and HVC, and these agents are now allotted a chapter of their own, Chapter 63. Chapter 64 describes chemotherapy for retroviruses. This present chapter covers antiviral agents for nonretroviral infections other than HVB and HVC.

Viral Replication and Drug Targets

Viruses are simple microorganisms that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a capsid. Some viruses also possess a lipid envelope derived from the infected host cell, which, like the capsid, may contain antigenic glycoproteins. Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit virus-directed rather than host cell-directed nucleic acid or protein synthesis (Table 62–1). Host cell molecules that are essential to viral replication also offer targets for intervention. Figure 62–1 gives a schematic diagram of the replicative cycle of typical DNA and RNA viruses with the sites of anti-viral drugs indicated.

DNA viruses include poxviruses (smallpox, herpesviruses (chickenpox, shingles, oral and genital herpes); adenoviruses (conjunctivitis, sore throat); hepadnaviruses (HBV); and papillomaviruses (warts). Most DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into mRNA by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. Poxviruses are an exception; they carry their own RNA polymerase and replicate in the host cell cytoplasm.

For RNA viruses, the replication strategy either relies on enzymes in the virion to synthesize mRNA or has the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA. Most RNA viruses complete their replication in the host cell cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses include rubella virus (German measles); rhabdoviruses (rabies); picornaviruses (poliomyelitis, meningitis, colds, hepatitis A); arenaviruses (meningitis, Lassa fever); flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C, Zika virus); orthomyxoviruses (influenza); paramyxoviruses (measles, mumps); and coronaviruses (cold, SARS). Retroviruses are RNA viruses that include HIV; chemotherapy for retroviruses is described in Chapter 64. Pharmacotherapy of viral hepatitis is covered separately in Chapter 63.

Table 62–2 summarizes currently approved drugs for nonretroviral infections, excluding those for viral hepatitis. Their pharmacological properties are presented in the material that follows, class by class, as listed in the table.

Antiviral Agents

Herpes simplex virus type 1 typically causes diseases of the mouth, face, skin, esophagus, or brain. HSV-2 usually causes infections of the genitals, rectum, skin, or meninges. Both cause serious infections in neonates. Agents used in treating HSV work by several mechanisms to inhibit viral DNA replication in the host cell (Figure 62–1; Table 62–1).

Acyclovir and Valacyclovir

Acyclovir is an acyclic guanine nucleoside analogue that lacks the 2’ and 3’ positions normally supplied by ribose. Valacyclovir is the l-valyl ester prodrug of acyclovir. Acyclovir is the prototype of a group of antiviral agents that are nucleoside congeners (see Figure 62–2) that are phosphorylated intracellularly by a viral kinase and subsequently by host cell enzymes to become inhibitors of viral DNA synthesis. Related agents include penciclovir and ganciclovir.

Mechanisms of Action and Resistance

Acyclovir inhibits viral DNA synthesis via a mechanism outlined in Figure 62–3. Its selectivity of action depends on interaction with HSV TK (thymidine kinase) and DNA polymerase. The initial phosphorylation of acyclovir is facilitated by HSV TK and thus occurs only in cells infected with the virus. The affinity of acyclovir for HSV TK is about 200 times
greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which competes for endogenous dGTP. The immunosuppressive agent mycophenolate mofetil (see Chapter 35) potentiates the antiprosopivirus activity of acyclovir and related agents by depleting intracellular dGTP pools. Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much lesser extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 5'-hydroxyl group. By a mechanism termed suicide inactivation, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.

Acyclovir resistance in HSV can result from impaired production of acyclovir triphosphate (0.8–4.0 μg/mL) and EBV, and least active against CMV (generally > 20 μg/mL) and HHV-6. Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (> 50 μg/mL).

**ADME**

The oral bioavailability of acyclovir is about 10%–30% and decreases with increasing dose (Wagstaff et al., 1994). Delivery of an oral dose can be enhanced by administration of the the prodrug form, valacyclovir. Valacyclovir is an esterified version with higher bioavailability (53%–70%) than acyclovir (Steingrimsdottir et al., 2000); deesterification occurs rapidly and nearly completely following oral administration. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptidase transporters. Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and CSF. Compared with plasma, salivary concentrations are low, and concentrations in vaginal secretion vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Peritoneal dialysis can be enhanced by administration of the prodrug form, valacyclovir.

**Therapeutic Uses**

Acyclovir's clinical use is limited to herpesviruses. Acyclovir is most active against HSV-1 (effective \( C_{90} \) range: 0.02–0.9 μg/mL), approximately half as active against HSV-2 (0.03–2.2 μg/mL), a tenth as potent against VZV (0.8–4.0 μg/mL) and EBV, and least active against CMV (generally > 20 μg/mL) and HHV-6. Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (> 50 μg/mL).
Figure 62–1  Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. The symbol indicates a block to virus growth. A. Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as TKs, DNA polymerases, and so on. After DNA replication, the bulk of the herpesvirus genes (called late genes) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions. B. Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAp complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus.

In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones. These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Because VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating VZV infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster. Acyclovir is ineffective therapeutically in established CMV infections, but ganciclovir is effective for CMV prophylaxis in immunocompromised patients. EBV-related oral hairy leukoplakia may improve with acyclovir.

Oral acyclovir in conjunction with systemic corticosteroids appears beneficial in treating Bell palsy; valacyclovir is ineffective in acute vestibular neuritis.

Herpes Simplex Virus Infections. In initial genital HSV infections, oral acyclovir (200 mg five times daily or 400 mg three times daily for 7–10 days) and valacyclovir (1000 mg twice daily for 7–10 days) are associated with significant reductions in virus shedding, symptoms, and time to healing (Kimberlin and Rouse, 2004). Intravenous acyclovir (5 mg/kg every 8 h) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical acyclovir is much less effective than systemic
administration. None of these regimens reproducibly reduces the risk of recurrent genital lesions. Acyclovir (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or valacyclovir (500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1–2 days. Frequently recurring genital herpes can be suppressed effectively with chronic oral acyclovir (400 mg twice daily or 200 mg three times daily) or with valacyclovir (500 mg or, for very frequent recurrences, 1000 mg once daily). During use, the rate of clinical recurrences decreases by about 90%, and subclinical shedding is markedly reduced, although not eliminated. Valacyclovir suppression of genital herpes reduces the risk of transmitting infection to a susceptible partner by about 50% over an 8-month period (Corey et al., 2004). Chronic suppression may be useful in those with disabling recurrences of herpetic whitlow or HSV-related erythema multiforme.

Oral acyclovir is effective in primary herpetic gingivostomatitis (600 mg/m² four times daily for 10 days in children) but provides only modest clinical benefit in recurrent orolabial herpes. Short-term, high-dose valacyclovir (2 g twice over 1 day) shortens the duration of recurrent orolabial herpes by about 1 day (Elish et al., 2004). The FDA has approved an acyclovir/hydrocortisone combination (Lipsovir) for early treatment of recurrent herpes cold sores. Topical acyclovir cream is modestly effective in recurrent labial (Spruance et al., 2002) and genital herpes simplex virus infections. Preexposure acyclovir prophylaxis (400 mg twice daily for 1 week) reduces the overall risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. Acyclovir during the last month of pregnancy reduces the likelihood of viral shedding and the frequency of cesarean delivery in women with primary or recurrent genital herpes (Corey and Wald, 2009).

In immunocompromised patients with mucocutaneous HSV infection, intravenous acyclovir (250 mg/m² every 8 h for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral acyclovir (800 mg five times per day) and valacyclovir (1000 mg twice daily) for 5–10 days are also effective. Recurrences are common after cessation of therapy and may require long-term suppression. In those with very localized labial or facial HSV infections, topical acyclovir may provide some benefit. Intravenous acyclovir may be beneficial in viscera- dely disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic acyclovir prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous acyclovir (250 mg/m² every 8–12 h) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral acyclovir (400 mg five times daily) is effective, and long-term oral acyclovir (200–400 mg three times daily for 6 months) also reduces the risk of VZV infection (Steer et al., 2000). In HSV encephalitis, acyclovir (10 mg/kg every 8 h for a minimum of 10 days) reduces mortality by more than 50% and improves overall neurologic outcome compared with vidarabine. Higher doses (15–20 mg/kg every 8 h) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous acyclovir (20 mg/kg every 8 h for 21 days) is more effective than lower doses in viscerally invasive neonatal HSV infections (Kimberlin et al., 2001). In neonates and immunosuppressed patients and, rarely, in previously healthy persons, relapses of encephalitis following acyclovir may occur. The value of continuing long-term suppression with valacyclovir after completing intravenous acyclovir is under study.

An ophthalmic formulation of acyclovir (not available in the U.S.) is at least as effective as topical vidarabine or trifluridine in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; however, in immunocompromised hosts, acyclovir-resistant HSV

![Chemical structures of some antiviral drugs](image-url)

**Figure 62–2** Chemical structures of some antiviral drugs. Many antiviral agents are nucleoside congeners that are phosphorylated sequentially by viral and host kinases to become triphosphate inhibitors of viral DNA synthesis (see Figure 62–3). Foscarnet is a pyrophosphate analogue that selectively blocks the pyrophosphate binding site on viral DNA polymerases, thereby inhibiting chain elongation.
isolates can cause extensive mucocutaneous disease and, rarely, meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 4% to 7% of immunocompromised patients receiving acyclovir treatment. Recurrences after cessation of acyclovir usually are due to sensitive virus but may be due to acyclovir-resistant virus in patients with AIDS. In patients with progressive disease, intravenous foscartern therapy is effective, and vidarabine is considered only when all other therapies have failed (Chilukuri and Rosen, 2003).

**Untoward Effects**

Acyclovir generally is well tolerated. Chronic acyclovir suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities has been recognized in infants born to women exposed to acyclovir during pregnancy (Ratanajamit et al., 2003). Topical acyclovir in a polyethylene glycol base may cause mucosal irritation and transient burning when applied to genital lesions. Oral acyclovir has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. Valacyclovir also may be associated with headache, nausea, diarrhea, nephrotoxicity, and CNS symptoms (confusion, hallucinations). Uncommon side effects include severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients. Acyclovir has been associated with neutropenia in neonates. The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Nephrotoxicity usually resolves with drug cessation and volume expansion. Hemodialysis may be useful in severe cases. Severe somnolence and lethargy may occur with combinations of zidovudine (see Chapter 59) and acyclovir. Concomitant cyclosporine and probably other nephrotoxic agents enhance the risk of nephrotoxicity. Probenecid decreases the acyclovir renal clearance and prolongs the elimination $t_{1/2}$. Acyclovir may decrease
Mechanisms of Action and Resistance

Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to about 30% of patients with retinitis by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

ADME

Cidofovir has very low oral bioavailability. Penetration into the CSF is low. Topical cidofovir gel may result in low plasma concentrations (<0.5 μg/mL) in patients with large mucocutaneous lesions. Plasma levels after intravenous dosing decline in a biphasic pattern with a terminal t½ that averages 2.6 h. The active form, cidofovir diphosphate, has a prolonged intracellular t½ and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one-sixth thousandth of those required to inhibit human DNA polymerases (Hitchcock et al., 1996). A phosphocholine metabolite also has a long intracellular t½ (about 87 h) and may serve as an intracellular reservoir of drug. The prolonged intracellular t½ of cidofovir diphosphate allows infrequent (weekly or biweekly) dosing regimens. Cidofovir is cleared by the kidney via glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine. Probenecid blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. Elimination relates linearly to creatinine clearance; the t½ increases to 32.5 h in patients on CAPD. Hemodialysis removes more than 50% of the administered dose.

Therapeutic Uses

Intravenous cidofovir is approved for the treatment of CMV retinitis in HIV-infected patients. Intravenous cidofovir has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients, and extensive molluscum contagiosum in HIV patients. Reduced doses without probenecid may be beneficial in BK virus nephropathy in patients with a renal transplant. Topical cidofovir gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intrarectal cidofovir induces remissions in adults and children with respiratory papillomatosis.

Untoward Effects

Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Concomitant oral probenecid and saline prehydration reduce the risk of renal toxicity; however, probenecid alters renal clearance of many agents, albeit not of cidofovir. For example, probenecid alters zidovudine pharmacokinetics such that zidovudine doses should be reduced when probenecid is present, as should the doses of other drugs whose renal secretion probenecid inhibits (e.g., β-lactam antibiotics, NSAIDs, acyclovir, lorazepam, furosemide, theophylline, and rifampin). On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10%–15% show an elevated serum creatinine concentration, and 15%–20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly, and low intraocular pressure occurs infrequently with intravenous cidofovir. Administration with food and pretreatment with antiemetics, antihistamines, or acetaminophen may improve tolerance. Concurrent nephrotoxic agents are contraindicated, and at least 7 days should elapse before initiation of cidofovir treatment is recommended after prior exposure to aminoglycosides, intravenous pentamidine, amphotericin B, foscarnet, NSAID, or contrast dye. Cidofovir and oral ganciclovir are poorly tolerated in combination at full doses.

Topical application of cidofovir is associated with dose-related application site reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. Cidofovir is considered a potential human carcinogen. It may cause infertility and is classified as pregnancy category C.

Famiciclovir and Penciclovir

Famiciclovir is the diacetyl ester prodrug of 6-deoxy penciclovir and lacks intrinsic antiviral activity. Penciclovir is an acyclic guanine nucleoside analogue. Penciclovir is similar to acyclovir in its spectrum of activity and potency against HSV and VZV. It also is inhibitory for HBV.

Mechanisms of Action and Resistance

Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral TK. Penciclovir triphosphate is a competitive inhibitor of viral DNA polymerase (see Figure 62–3). Although penciclovir triphosphate is approximately a one-hundredth as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in infected cells at much higher concentrations and for more prolonged periods. The prolonged intracellular t½ of penciclovir triphosphate, 7–20 h, is associated with prolonged antiviral effects. Because penciclovir has a 3′-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation. Resistance during clinical use is low. TK-deficient, acyclovir-resistant herpesviruses are cross-resistant to penciclovir.

ADME

Oral penciclovir has low (<5%) bioavailability. In contrast, famciclovir is well absorbed orally (bioavailability ~75%) and is converted rapidly to penciclovir by deacetylation of the side chain and oxidation of the purine ring during and following absorption. Food slows absorption but does not reduce overall bioavailability. The plasma elimination t½ of penciclovir averages about 2 h, and more than 90% is excreted unchanged in the urine. Following oral famciclovir administration, nonrenal clearance accounts for about 10% of the dose, primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor (<10% of dose) are eliminated primarily in the urine. The plasma t½ averages 9.9 h in renal insufficiency (ClCr < 30 mL/min); hemodialysis efficiently removes penciclovir.

Therapeutic Uses

Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for managing HSV and VZV infections.

Oral famciclovir (250 mg three times a day for 7–10 days) is as effective as acyclovir in treating first-episode genital herpes (Kimberlin and Rouse, 2004). In patients with recurrent genital HSV, patient-initiated famciclovir treatment (125 or 250 mg twice daily for 5 days) reduces healing time and symptoms by about 1 day. Famciclovir (250 mg twice daily for up to 1 year) is effective for suppression of recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice daily) reduce HSV recurrences in HIV-infected persons. Intravenous penciclovir (5 mg/kg every 8 or 12 h for 7 days) (not available in the U.S.) is comparable to intravenous acyclovir for treating mucocutaneous HSV infections in
immunocompromised hosts. In immunocompetent persons with recurrent orolabial HSV, topical 1% penciclovir cream (applied every 2 h while awake for 4 days) shortens healing time and symptoms by about 1 day (Raborn et al., 2002).

In immunocompetent adults with herpes zoster of 3 days’ duration or less, famciclovir (500 mg three times a day for 10 days) is at least as effective as acyclovir (800 mg five times daily) in reducing healing time and zoster-associated pain, particularly in those 50 years or older. Famciclovir is comparable with valaciclovir in treating zoster and reducing associated pain in older adults (Tyring et al., 2000). Famciclovir (500 mg three times a day for 7–10 days) also is comparable with high-dose oral acyclovir in treating zoster in immunocompromised patients and in those with ophthalmic zoster (Tyring et al., 2001).

Famiclovir is associated with dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than lamivudine (Lai et al., 2002). Famciclovir is also ineffective in treating lamivudine-resistant HBV infections owing to emergence of multiply resistant variants.

Untoward Effects
Oral famciclovir is associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical penciclovir (~1%) is rarely associated with local reactions. The short-term tolerance of famciclovir is comparable with that of acyclovir. Penciclovir is mutagenic at high concentrations. Long-term administration (1 year) does not affect spermatogenesis in men. Safety during pregnancy has not been established.

Ganciclovir and Valganciclovir
Ganciclovir is an acyclic guanine nucleoside analogue that is similar in structure to acyclovir. Valganciclovir is the β-valeryl ester prodrug of ganciclovir. Ganciclovir has inhibitory activity against all herpesviruses and is especially active against CMV.

Mechanisms of Action and Resistance
Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral TK during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by host enzymes. At least 10-fold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of dGTP incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (see Figures 62–1A to 62–3).

Cytomegalovirus can become resistant to ganciclovir by either of two mechanisms: reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase and mutations in viral DNA polymerase. Highly resistant variants with both mutations are cross-resistant to cidofovir and variably to foscarnet. Ganciclovir also is much less active against acyclovir-resistant TK-deficient HSV strains.

ADME
The oral bioavailability of ganciclovir is low, only 6%–9% following ingestion with food. On the other hand, oral doses of the prodrug valganciclovir are well absorbed and hydrolyzed rapidly to ganciclovir; thus, valganciclovir provides greater bioavailability of the valaciclovir moiety, about 60%. Food further increases the bioavailability of valganclovir by about 25%. Following intravenous administration of ganciclovir, vitreous fluid levels are similar to or higher than those in plasma and decline with a \( t_{1/2} \) of 23–26 h. Intracocular sustained-release ganciclovir implants provide vitreous levels of about 4.1 μg/mL. The plasma elimination \( t_{1/2} \) is about 2–4 h. Intracellular ganciclovir triphosphate concentrations are 10-fold higher than those of acyclovir triphosphate and decline much more slowly, with an intracellular elimination \( t_{1/2} \) longer than 24 h. These differences may account in part for ganciclovir’s greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections.

Over 90% of ganciclovir is eliminated unchanged by renal excretion. Plasma \( t_{1/2} \) increases in patients with severe renal insufficiency.

Therapeutic Uses
In CMV retinitis, initial induction treatment (5 mg/kg IV every 12 h for 10–21 days) is associated with improvement or stabilization in about 83% of patients (Faulds and Heel, 1990). Reduced viral excretion is usually evident by 1 week, and funduscopic improvement is seen by 2 weeks. Because of the high risk of relapse, patients with AIDS with retinitis require suppressive therapy with high doses of ganciclovir (5 mg/kg/d). Oral ganciclovir (1000 mg three times daily) is effective for suppression of retinitis after initial intravenous treatment but has been replaced in practice by oral valganciclovir. Oral valganciclovir (900 mg twice daily for 21 days of initial treatment) is comparable with intravenous dosing for initial control and sustained suppression (900 mg daily) of CMV retinitis (Schreiber et al., 2009). Intravitreal ganciclovir injections have been used in some patients, and an intracocular sustained-release ganciclovir implant is more effective than systemic dosing in suppressing retinitis progression.

Ganciclovir therapy (5 mg/kg every 12 h for 14–21 days) may benefit other CMV syndromes in patients with AIDS or recipients of solid-organ transplants (Kotton et al., 2010). Ganciclovir has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients (Schreiber et al., 2009).

A ganciclovir opthalmic gel formulation (Zirgan) is effective in treating HSV keratitis (Colin et al., 1997). Oral ganciclovir also reduces HBV DNA levels and aminotransferase levels in chronic hepatitis B virus infection (Hadziyannis et al., 1999), but the drug is not approved for this indication.

Untoward Effects
Myelosuppression is the principal dose-limiting toxicity of ganciclovir. Neutropenia occurs in about 15%–40% of patients and is observed most commonly during the second week of treatment and usually is reversible within 1 week of drug cessation. Persistent fatal neutropenia has occurred. Recombinant G-CSF (filgrastim, lenograstim) may be useful in treating ganciclovir-induced neutropenia (see Chapter 41). Thrombocytopenia occurs in 5%–20% of patients. Zidovudine and probably other cytoxic agents increase the risk of myelosuppression, as do nephrotoxic agents that impair ganciclovir excretion. Probenecid and possibly acyclovir reduce renal clearance of ganciclovir. Oral ganciclovir increases the absorption and peak plasma concentrations of didanosine by approximately 2-fold and that of zidovudine by about 20%. CNS side effects (5%–15%) range in severity from headache to behavioral changes to convulsions and coma. About one-third of patients must interrupt or temporarily stop intravenous ganciclovir therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea or vomiting, and eosinophilia also have been described. Ganciclovir is classified as pregnancy category C (risk not ruled out).

Foscarnet
Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analogue that is inhibitory for all herpesviruses and HIV.

Mechanisms of Action and Resistance
Foscarnet inhibits viral nucleic acid synthesis by interacting directly at HSV DNA polymerase or HIV reverse transcriptase (see Figures 62–1A and 62–3). Foscarnet reversibly blocks the pyrophosphate binding site of the viral DNA polymerase, inhibiting cleavage of pyrophosphate from deoxynucleotide triphosphates and thereby inhibiting chain elongation (deoxynucleotide triphosphate + DNA → diphosphate + DNA-C). Foscarnet has about 100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerases α. Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase.

ADME
Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration; in addition, the drug’s oral bioavailability is low.
Vitreous levels approximate those in plasma; CSF levels average 66% of those in plasma at steady state. Over 80% of foscarnet is excreted unchanged in the urine. Dose adjustments are necessary for small decreases in renal function. Plasma elimination has initial bimodal half-lives totaling 4–8 h and a prolonged terminal elimination t½ of 3–4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10%–20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).

**Therapeutic Uses**

Intravenous foscarnet is effective for treatment of CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections.

In CMV retinitis in patients with AIDS, foscarnet (60 mg/kg every 8 h or 90 mg/kg every 12 h for 14–21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is associated with clinical stabilization in about 90% of patients. In CMV retinitis in patients with AIDS, foscarnet (60 mg/kg every 8 h or 90 mg/kg every 12 h for 14–21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is associated with clinical stabilization in about 90% of patients. When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, foscarnet (60 mg/kg every 12 h for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous ganciclovir and causes less neutropenia (Reusser et al., 2002). When used for CMV infections, foscarnet may reduce the risk of Kaposi sarcoma in HIV-infected patients. Intravitreal injections of foscarnet have also been used. In acyclovir-resistant mucocutaneous HSV infections, lower doses of foscarnet (40 mg/kg every 8 h for 2–7 days) are associated with cessation of viral shedding and with complete healing of lesions in about three-quarters of patients. Foscarnet also appears to be effective in acyclovir-resistant VZV infections. Topical foscarnet cream is ineffective in treating recurrent genital HSV in immunocompetent persons but appears to be useful in chronic acyclovir-resistant infections in immunocompromised patients.

**Untoward Effects**

Major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are generally reversible after cessation. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Saline loading may reduce the risk of nephrotoxicity. Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in Ca²⁺ and phosphate, hypomagnesemia, and hypokalemia. Concomitant intravenous pentamidine administration increases the risk of symptomatic hypocalcemia. CNS side effects include headache (25%), tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation and ulceration, and oral foscarnet may cause GI disturbance. Preclinical studies indicate that high foscarnet concentrations are mutagenic. Safety in pregnancy or childhood is uncertain.

**Fomivirsen**

Fomivirsen, a 21-base phosphorothioate oligonucleotide, provides antisense therapy. The drug is complementary to the mRNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to ganciclovir, foscarnet, and cidofovir. Fomivirsen is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous (t½ ~ 55 h) through distribution to the retina and probable exonuclease digestion. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen injections (330 μg weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression. Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15%–20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions. This drug is no longer available in the U.S.

**Docosanol**

Docosanol is a long-chain saturated alcohol that is approved as an over-the-counter 10% cream for the treatment of recurrent orolabial herpes. Docosanol inhibits the in vitro replication of many lipid-enveloped viruses, including HSV. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibits viral entry into the cell. Topical treatment beginning within 12 h of prodromal symptoms or lesion onset reduces healing time by about 1 day and is well tolerated. Treatment initiation at papular or later stages provides no benefit.

**Idoxuridine**

Idoxuridine is an iodinated thymidine analogue that inhibits the in vitro replication of various DNA viruses, including herpesviruses and poxviruses. Idoxuridine lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. In the U.S., idoxuridine is approved only for topical (ophthalmic) treatment of HSV keratitis. Idoxuridine formulated in dimethylsulfoxide is available outside the U.S. for topical treatment of herpes labialis, genitalis, and zoster. Adverse reactions include pain, pruritus, inflammation, and edema of the eye or lids; allergic reactions are rare.

**Trifluridine**

Trifluridine is a fluorinated pyrimidine nucleoside that has in vitro inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adeno viruses. Trifluridine inhibits replication of herpesviruses, including acyclovir-resistant strains, and also inhibits cellular DNA synthesis at relatively low concentrations. Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate is a competitive inhibitor of thymidine triphosphate incorporation into DNA; trifluridine is incorporated into viral and cellular DNA. Trifluridine-resistant HSV has been described.

Trifluridine currently is used for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions and irritation are uncommon. Topical trifluridine also appears to be effective in some patients with acyclovir-resistant HSV cutaneous infections.

**Anti-influenza Agents**

Recently, there has been concern about the possibility of new influenza pandemics stemming from small but severe outbreaks of H5N1 avian influenza and the novel 2009 influenza A H1N1, thought to be of swine origin. Five drugs are currently approved for the treatment and prevention of influenza virus infection: the adamantane antivirals, amantadine and rimantadine; oseltamivir; zanamivir; and peramivir. Resistance to these drugs has arisen as a consequence of their overuse, including in veterinary applications. Development of resistance and the spread of resistant viruses are major challenges in the chemotherapy and chemoprophylaxis of influenza and are likely to drive future recommendations for use of these drugs in global populations. The CDC annually issues recommendations for influenza vaccinations and comments on effective medications (CDC, 2016).
Amantadine and Rimantadine

Amantadine and its derivative rimantadine are uniquely configured tricyclic amines. Rimantadine has \( \text{H}_3\text{C} \rightarrow \text{CH} \rightarrow \text{NH}_2 \) in place of the –NH₂ group.

Mechanisms of Action and Resistance

Amantadine and rimantadine inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly, probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH–induced conformational changes in hemagglutinin during its intracellular transport later in replication. Resistance to these drugs results from a mutation in the RNA sequence encoding for the M2 protein transmembrane domain; resistant isolates typically appear in the treated patient within 2–3 days of starting therapy.

ADME

Table 62–3 summarizes important pharmacokinetics properties of these antiviral agents. The two adamantanes differ in several respects. Amantadine is excreted largely unmetabolized in the urine (\( t_{1/2} \) of elimination is ~12–18 h in young adults, increasing up to twice that in the elderly and even more in those with renal impairment). By contrast, elimination of rimantadine depends on hepatic function; the drug is subject to phase 1 and phase 2 reactions prior to renal excretion of metabolites (elimination \( t_{1/2} \sim 24–36 \) h; 60%–90% is excreted in the urine as metabolites). The elderly require only one-half the weight-adjusted dose of amantadine needed for young adults. Amantadine is excreted in breast milk. Rimantadine concentrations in nasal mucus average 50% higher than those in plasma.

Therapeutic Uses

Although both drugs are useful for the prevention and treatment of infections caused by influenza A virus, vaccination against influenza is a more cost-effective means of reducing disease burden. Amantadine and rimantadine are active only against susceptible influenza A viruses (not influenza B); rimantadine is 4–10-fold more active than amantadine. Virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs.

Seasonal prophylaxis with either amantadine or rimantadine (a total of 200 mg/d in one or two divided doses in young adults) is about 70%–90% protective against influenza A illness. These agents are efficacious in preventing nosocomial influenza and in curtailing nosocomial outbreaks during pandemic influenza. Doses of 100 mg/d are better tolerated and still appear to be protective against influenza illness. Seasonal prophylaxis is an alternative in high-risk patients, if the influenza vaccine cannot be administered or may be ineffective (i.e., in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4–8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

The amantadines are effective against influenza A H1N1 if treatment is initiated within 2 days of the onset of symptoms (Schmidt, 2004). In uncomplicated influenza A illness of adults, early amantadine or rimantadine treatment (200 mg/d for 5 days) reduces the duration of fever and systemic complaints by 1–2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding. The usual regimen in children (≥1 year of age) is 5 mg/kg/d, up to 150 mg, administered once or twice daily. Resistant variants have been recovered from about 30% of treated children or outpatient adults by the fifth day of therapy.

³For antivirally active oseltamivir carboxylate.  
⁴Inhaled formulation only.  
⁵% of parent drug.  
⁶Types of influenza.
The most common side effects related to amantadine and rimantadine are minor dose-related CNS and GI effects: nervousness, light-headedness, difficulty concentrating, insomnia, loss of appetite, and nausea. CNS side effects (5%–33%) occur in patients treated with amantadine at doses of 200 mg/d but are significantly less frequent with rimantadine. The neurotoxic effects of amantadine appear to be increased by concomitant ingestion of antihistamines and psychotropic or anticholinergic drugs, especially in the elderly. At comparable doses of 100 mg/d, rimantadine is significantly better tolerated in nursing home residents than amantadine. High amantadine plasma concentrations (1.0–5.0 μg/mL) have been associated with serious neurotoxic reactions, including delirium, hallucinations, seizures, coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Both drugs are considered pregnancy category C (risk not ruled out; see Appendix I).

Oseltamivir

Oseltamivir carboxylate is a transition-state analogue of sialic acid that is a potent selective inhibitor of the neuraminidases of influenza A and B virus. Oseltamivir phosphate is an ethyl ester prodrug that lacks antiviral activity. Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of zanamivir: It inhibits amantadine- and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

Mechanisms of Action and Resistance

Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in proenyn viros, and in respiratory secretions. This enzymatic action is essential for release of virus from infected cells. Interaction of oseltamivir carboxylate with the neuraminidase causes a conformational change within the enzyme's active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract. Influenza variants selected in vitro for resistance to oseltamivir carboxylate contain hemagglutinin or neuraminidase mutations. Seasonal influenza A (H1N1) has become virtually 100% resistant to oseltamivir worldwide (Moscona, 2009; Schirmer and Holodniy, 2009). Importantly, novel H1N1 (nH1N1 or swine influenza) remains susceptible to oseltamivir.

ADME

Table 62–3 summarizes important pharmacokinetics properties of oseltamivir carboxylate. Oral oseltamivir phosphate is absorbed rapidly and cleaved by esterases in the GI tract and liver to the active carboxylate. Food does not decrease bioavailability but reduces the risk of GI intolerance. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. Probenecid doubles the plasma t1/2 of the carboxylate, which indicates tubular secretion by the anionic pathway. Children younger than 2 years exhibit age-related changes in oseltamivir carboxylate clearance and total drug exposure (Kimberlin et al., 2009).

Therapeutic Uses

Oseltamivir is effective in the treatment and prevention of influenza A and B virus infections. Treatment of previously healthy adults (75 mg twice daily for 5 days) or children 1–12 years of age (weight-adjusted dosing) with acute influenza reduces illness duration by about 1–2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40%–50%. Treatment reduces by about 50% the risk of subsequent hospitalization in adults (Kaiser et al., 2003). When used for prophylaxis during the typical influenza season, oseltamivir (75 mg once daily) is effective (~70%–90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents; short-term use protects against influenza in household contacts (Schirmer and Holodniy, 2009).

Untoward Effects

Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis. GI complaints typically resolve in 1–2 days despite continued dosing and are preventable by administration with food. An increased frequency of headache was reported in one prophylaxis study in elderly adults. Neither the phosphate nor the carboxylate form interacts with CYPs in vitro. Oseltamivir does not appear to impair fertility, but safety in pregnancy is uncertain (pregnancy category C).

Zanamivir

Zanamivir is a sialic acid analogue that potently and specifically inhibits the neuraminidases of influenza A and B viruses. Zanamivir inhibits in vitro replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants.

Mechanisms of Action and Resistance

Zanamivir inhibits viral neuraminidase and thus causes viral agglomeration at the cell surface and reduced spread of virus within the respiratory tract. In vitro selection of viruses resistant to zanamivir is associated with mutations in the viral hemagglutinin or neuraminidase. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir-resistant variants usually have decreased infectivity in animals.

ADME

Table 62–3 summarizes important pharmacokinetics properties of zanamivir. Oral bioavailability of zanamivir is less than 5%, and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath actuated and requires a cooperative patient. Following inhalation of the dry powder, about 15% is deposited in the lower respiratory tract and about 80% in the oropharynx. Overall bioavailability is 4%–17%.

Depending on the strain, zanamivir competitively inhibits influenza neuraminidase activity at concentrations of about 0.2–3 ng/mL but affects neuraminidases from other pathogens and mammalian sources only at 100-fold higher concentrations. Zanamivir inhibits in vitro replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants. It is active after topical administration in animal influenza models.

Therapeutic Uses

Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections. Early zanamivir treatment (10 mg [two inhalations] twice daily for 5 days) of febrile influenza in ambulatory adults and children 5 years or older shortens the time to illness resolution by 1–3 days and in adults reduces by 40% the risk of lower respiratory tract complications that require use of antibiotics. Once-daily inhaled zanamivir is highly protective against community-acquired influenza illness, and when given for 10 days, it protects against household transmission. Intravenous zanamivir (t1/2 ~ 1.7 h) is available in the U.S. as an EIND and in the E.U. on a compassionate use basis for life-threatening, resistant influenza.

Untoward Effects

Orally inhaled zanamivir generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. Zanamivir is not generally recommended for treatment of patients with underlying airway disease because of the risk of serious adverse events. Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy risk not ruled out). No clinically significant drug interactions have been recognized to date. Zanamivir does not diminish the immune response to injected influenza vaccine.

Peramivir

Peramivir is a recently FDA-approved inhibitor of influenza virus neuraminidase, indicated for the treatment of acute uncomplicated influenza in patients 18 years and older who have been symptomatic for no
Mechanisms of Action and Resistance
Peramivir has a mechanism of action similar to that of other neuraminidase inhibitors. Neuraminidase resistance can occur as the result of point mutations in either the neuraminidase or hemagglutinin genes or both. Structurally, peramivir differs somewhat from others in the class via a substitution resulting in multiple binding site interactions, which confers some activity against cross-resistant viruses. Antiviral resistance is currently low to the three available neuraminidase inhibitors amongst circulating influenza viruses. This will likely change with each influenza season. In general, cross-resistance across these agents exists. The degree of cross-resistance depends on the viral strain and which point mutations occur.

ADME
Peramivir is not significantly metabolized in humans. It is not a substrate for CYPs or a substrate or inhibitor of P-glycoprotein. The elimination half-life following intravenous administration of 600 mg as a single dose is approximately 20 h. The major route of clearance is via renal excretion. Approximately 90% of total clearance is unchanged peramivir. Negligible accumulation was observed after multiple dosing. Following a 600-mg dose infused over 30 min, the end-of-infusion C_{max} was 46.8 μg/mL, and the AUC_{max} was 102.7 μg h/mL. Dosing should be adjusted in patients with altered creatinine clearance. A single 200-mg dose should be administered for those with an estimated creatinine clearance (CL_{CR}) of 10−29 mL/min. No clinically significant drug interactions have been recognized to date.

Therapeutic Uses
Peramivir is administered as a single 600-mg dose, administered via intravenous infusion over 15–30 min. A phase II clinical trial demonstrated that intravenous peramivir (300 or 600 mg as a single-dose infusion) reduced the time to alleviation of symptoms, from 82 h (placebo) to 59 h (treatment with 600 mg peramivir) (Kohno et al., 2010). A phase III trial demonstrated that peramivir (300 or 600 mg) was comparable to placebo in extent of symptom relief to oral oseltamivir (75 mg twice a day for 5 days) in patients with seasonal influenza A or B, and with comparable rates of adverse events (Kohno et al., 2011). At present, peramivir’s primary use may be limited to patients with acute, uncomplicated influenza who cannot absorb or for other reasons cannot take oral agents. Further studies are needed regarding the use of peramivir in severely ill hospitalized patients and in the pediatric population.

Untoward Effects
The most common adverse event (>2%) is diarrhea. Hypersensitivity reactions (e.g., Stevens-Johnson syndrome and erythema multiforme) have occurred, and treated patients with influenza may be at increased risk for neuropsychiatric events such as hallucinations, delirium, and abnormal behavior. Frequency and severity of adverse effects (peramivir 300 mg or 600 mg) are comparable to those with oseltamivir (75 mg twice daily for 5 days) (Kohno et al., 2011). Patients receiving 600 mg peramivir or oseltamivir had decreased neutrophil counts (10.4% vs. 9.3%), diarrhea (8.2% vs. 7.4%), and vomiting (1.6% vs. 4.1%), respectively.

Interferon
Interferons are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative activities (see Chapter 35). Three major classes of human IFNs with significant antiviral activity are α, β, and γ. Clinically used recombinant α-IFNs are nonglycosylated proteins of about 19,500 Da, the pegylated forms predominating in the U.S. market. The mechanism of action, ADME, untoward effects, and therapeutic uses of IFNs are covered in Chapter 63. Recombinant, natural, and pegylated IFNs currently are approved in the U.S. for treatment of condyloma acumina, chronic HCV infection, chronic HBV infection, Kaposi sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis. In addition, IFNs have been granted orphan drug status for a variety of rare disease states, including idiopathic pulmonary fibrosis, laryngeal papillomatosis, juvenile rheumatoid arthritis, and infections associated with chronic granulomatous disease.

Papillomavirus
In refractory condylomata acuminata (genital warts), intraliansal injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36%−62% of patients, but other treatments are preferred. Relapse occurs in 20%–30% of patients. Verruca vulgaris may respond to intraliansal IFN-α. Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients.

Other Viruses
Interferons have been shown to have virological and clinical effects in various herpesvirus infections, including genital HSV infections, localized herpes zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections. In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of zidovudine and IFN is associated with only transient benefit and excessive hematological toxicity. IFN-α (3 million units thrice weekly) is effective for treatment of HIV-related thrombocytopenia that is resistant to zidovudine therapy. Interferon has broad-spectrum antiviral activity against respiratory viruses other than adenovirus. However, prophylactic intranasal IFN-α is protective only against rhinovirus colds, and chronic use is limited by the occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus colds.

</table>

Hepatitis viruses cause inflammation and necrosis of the liver. Hepatitis A and E, which are transmitted via the fecal-oral route, are typically self-limiting, although a small percentage (1%-2%) of those infected will develop fulminant hepatic failure. HBV, HCV, and hepatitis D viruses, however, are transmitted parenterally: Hepatitis B and C may or may not cause symptoms of acute infection, but both may progress to chronic infection. Individuals with chronic hepatitis B or C infection are at risk for cirrhosis, liver failure, and hepatocellular carcinoma. There are two notable differences between HBV and HCV. First, HBV is a vaccine-preventable illness, whereas there is no vaccine available to prevent HCV. Second, HCV can be cured with effective treatment, whereas the current treatments for HBV are not completely curative. The hepatitis D virus is defective and requires the presence of the HBV to propagate. Individuals coinfected with hepatitis B and D are at greater risk for cirrhosis and hepatocellular carcinoma compared with individuals with only hepatitis B infection, but fortunately only about 5% of individuals with HBV are coinfected with hepatitis D.

There are no antiviral therapies available for the treatment of hepatitis A and E viruses. At this time, the only drug available to treat hepatitis D is pegIFN-a, and it is successful in only 20%-35% of patients (Durantel and Zoulim, 2016). A number of drugs are available for the treatment of hepatitis B and C. Indeed, the RdRp (NS5B), the NSSA replication complex, and the NS3 protease of HCV have been fruitful targets for drug development over the past decade. We now have a growing number of DAAs that inhibit HCV RdRp, the NS3 protease, and NSSA. These DAAs, often used in oral combination therapies, have revolutionized the treatment of HCV, have good safety profiles, and provide well-tolerated and very effective treatments for HCV infection. Available therapies for HCV include IFN and nucleoside and nucleotide analogues. Several agents are used in various stages of clinical development for the treatment of HBV. Therapeutic strategies for these two chronic viral infections, hepatitis B and C, are very different and are described separately in this chapter.

Several agents employed against hepatitis viruses, including IFN, ribavirin, and the nucleoside/nucleotide analogues lamivudine, emtricitabine, and tenofovir, are also used to treat other conditions, described in Chapters 64 (Antiretroviral Agents and Treatment of HIV Infection) and 69 (Ocular Pharmacology).

Assessing the stage and severity of liver disease is an important aspect of treating individuals with chronic viral hepatitis. Individuals with cirrhosis require additional monitoring for potential complications (e.g., varices and hepatocellular carcinoma) and the approach to treatment differs in cirrhotics and decompensated cirrhotics compared to individuals without significant liver fibrosis. Cirrhosis can be diagnosed with histologic, radiographic, or laboratory tests. However, decompensated cirrhosis (also known as end-stage liver disease) is a clinical diagnosis based on the presence of variceal hemorrhage, ascites, jaundice, or hepatic encephalopathy. Decompensated cirrhosis carries a high risk of mortality (median survival 2 years), and these individuals should be evaluated for liver transplantation.

The urgency for liver transplantation in individuals with decompensated cirrhosis is determined using the MELD score. A MELD score is calculated based on a patient’s bilirubin, INR, and serum creatinine. Individuals with higher MELD scores have a higher risk for mortality and a more urgent need for transplantation. Cirrhosis may also be categorized based on the Child Pugh score. The Child Pugh score accounts for bilirubin, albumin, and INR values and the presence/absence of ascites and encephalopathy. Higher scores are associated with more advanced disease: mild hepatic impairment (Child Pugh category A; score of 5–6), moderate hepatic impairment (Child Pugh category B; score of 7–9), and severe hepatic impairment (Child Pugh category C; score of 10–15). Individuals with Child Pugh B and C scores have decompensated cirrhosis. Familiarity with MELD and Child Pugh scoring and the diagnoses of compensated versus decompensated cirrhosis is helpful for understanding the pharmacologic basis of hepatitis B and C treatment.

### Hepatitis B Virus

#### HBV Overview

Worldwide, an estimated 2 billion people have been infected with HBV and approximately 240 million have chronic disease (WHO, 2015). Areas with the highest HBV endemicity are sub-Saharan Africa and countries in the WHO Western-Pacific region (e.g., China) (Schweitzer et al., 2015). In these regions, HBV is most likely acquired perinatally. Those infected at birth have a 90% risk of progressing to chronic disease; otherwise, the risk of chronic HBV disease in adults is 5% (Tong and Revill, 2016). The lifetime risk of developing cirrhosis, liver failure, or hepatocellular carcinoma in individuals with HBV is 15%-40% (Lin et al., 2016). There are about 686,000 HBV-related deaths annually, which makes HBV the leading cause of liver-related deaths worldwide (WHO, 2016).

#### Genetic Heterogeneity of HBV

There are 10 described HBV genotypes (A–J) and at least 35 subtypes with distinct geographical distributions (Tong and Revill, 2016). Genotype A is most frequent in North America and Africa, genotypes B and C are dominant throughout East Asia and are primarily transmitted via the perinatal route, and genotype D is most common in Southern Europe and India.
HBV Genome and Life Cycle

Hepatitis B virus is a small, enveloped, partially double-stranded DNA virus approximately 3200 kb in length. The virus is composed of a nucleocapsid core (HBcAg, core antigen) surrounded by an outer lipoprotein envelope containing the surface antigen (HBsAg). HBV is compact and contains four overlapping ORF. ORF C encodes the nucleocapsid protein and HBcAg. ORF P encodes the polymerase and terminal protein, ORF S/pre-S encodes three envelope proteins, and ORF X encodes the regulatory X protein.

Figure 63–1 depicts the HBV life cycle (Brahmania et al., 2016; Lin et al., 2016; Tong and Revill, 2016). HBV virus binds to the NTCP (SLC10A1; also called LBAT) on the surface of the hepatocytes. Virus is taken up into the hepatocyte, where is it uncoated. The partially double-stranded DNA is brought into the host cell’s nucleus. The partial double strand is then repaired to form cccDNA. The cccDNA is not eliminated by available treatments; thus, a complete cure is not currently possible. cccDNA complexes with host proteins to form a minichromosome that becomes a template for the transcription of the various virally derived RNAs. These RNAs are transported to the cytoplasm, and some of the smaller RNAs are then made into various viral proteins, including the envelope protein. These proteins can actually be released without any genetic material (known as subviral particles). Filamentous and spherical HBsAg particles are produced in 3–4 log excess over virions (complete virus particles). These subvirus particles are thought to contribute to immune tolerance and T-cell exhaustion by increasing the amount of antigen that is circulating. The larger pregenomic RNA is used to form the HBcAg protein, which is also encapsidated. In the capsid, HBV is reverse transcribed to make more HBV DNA, and then the virus becomes bound to proteins and released as a virion.

Some patients develop mutations in the HBV genome that prevent HBcAg formation despite active HBV replication; this condition is known as HBeAg(−) disease.

HBV Drug Targets and Treatment Approach

Hepatitis B virus is a dynamic condition. Individuals with chronic infection can pass through several phases of disease throughout their lifetimes. At present, treatment is typically reserved for individuals with high levels of circulating HBV DNA and alanine aminotransferase elevations, those with cirrhosis, or for prevention of reactivation of disease in those receiving immunosuppressive therapies (e.g., chemotherapy) (Terrault et al., 2016). When treatment is necessary, the approach to HBV therapy in children and adults is similar, but most children have normal alanine aminotransferase levels and do not require treatment.

Current HBV therapies cannot achieve a complete cure, and only a small proportion (~10%) of patients achieve a functional cure. A functional cure is defined as undetectable HBV DNA with seroconversion from HBsAg to anti-HBs. This is analogous to a resolved acute infection, but cccDNA persists, which can lead to reactivation of the disease. Existing treatment options include pegIFN-α, which has nonspecific antiviral and immunomodulatory effects, or the nucleoside/tide analogues (Figure 63–2) adeovir, entecavir, lamivudine, telbivudine, and tenofovir, which inhibit the HBV polymerase. IFN treatment is finite (48–52 weeks), whereas individuals may require lifelong treatment with nucleoside/tide analogues. Entecavir and TDF are the preferred nucleoside/tide therapies due to

2′-5′(A)′: 2′-5′-oligoadenylate
AASLD: American Association for the Study of Liver Diseases
ADME: absorption, distribution, metabolism, excretion
ALT: alanine aminotransferase
anti-HB: hepatitis B surface antibody
AST: aspartate aminotransferase
AUC<sub>ss</sub>: area under the plasma concentration-time curve at steady state
BCRP: breast cancer resistance protein
BMI: body mass index
cccDNA: covalently closed circular DNA
C<sub>max</sub>, C<sub>mean</sub>: maximal blood or plasma concentration
C<sub>AUC</sub>: plasma concentration at steady state
CSF: cerebrospinal fluid
cYP: cytochrome P450
DAA: direct-acting antiviral
dATP: deoxyadenosine triphosphate
dCVR: deacetylase/sorafenib fixed-dose combination
dNTP: deoxynucleotide triphosphate
EBR: elbasvir
eGFR: estimated glomerular filtration rate
eIF-2: eukaryotic initiation factor
esRD: end-stage renal disease
FDA: Food and Drug Administration
gTP: guanosine triphosphate
GZR: grazoprevir
HBeAg: hepatitis B e antigen
HBeAg: hepatitis B surface antigen
HINT1: histidine triad nucleotide-binding protein 1
IFN: interferon
INR: international normalized ratio
LBAT: liver bile acid transporter
LDV/SOF: ledipasvir/sofosbuvir fixed-dose combination
MELD: model for end-stage liver disease
MHC: major histocompatibility complex
MRP: multidrug resistance protein
MU: million units
NTCP: Na<sup>+</sup>/taurocholate cotransporter
ORF: open reading frame
PEG: polyethylene glycol
pegIFN: pegylated interferon
Pgp: P-glycoprotein
PPi: proton pump inhibitor
PrO: paritaprevir/ritonavir-boosted, ombitasvir combination
PrOD: paritaprevir/ritonavir-boosted, ombitasvir, dasabuvir combination
RAV: resistance-associated variant
RdRp: RNA-dependent RNA polymerase
RT: reverse transcriptase
SIM/SOF: siprivir and sofosbuvir coadministered
SOF: sofosbuvir
SVR: sustained virologic response
TAF: tenovifor alfamidine fumarate
TDF: tenovifor disopropyl fumarate
VEL/SOF: fixed-dose combination of VEL and SOF
VEL: velpatasvir
WHO: World Health Organization

Genotype E is largely restricted to sub-Saharan Africa, while genotypes F and H cocirculate in indigenous peoples of South America. Genotypes I and J have been described in only three individuals and one individual, respectively.

Genotypes have relevance for the clinical manifestation of infection and the response to antiviral therapy. Clinically relevant features of HBV genotypes include the rate and durability of HBeAg loss (or seroconversion; A and D > B and C), the risk of developing aggressive HBeAg(−) chronic hepatitis C (B and D > A), spontaneous HBeAg loss (B > C), cirrhosis (C), hepatocellular carcinoma (C in Asians, F in Alaska Natives), and response to antivirals (A and B > C and D).
Figure 63–1  *Hepatitis B* life cycle. Not all steps in the hepatitis B viral life cycle have been completely elucidated. The figure represents our current understanding. For further details, consult the following references: Brahmania et al., 2016; Liang et al., 2015; and Tong and Revill, 2016.

CHAPTER 63
TREATMENT OF VIRAL HEPATITIS (HBV/HCV)

Clinical Implications of HBV Resistance

Hepatitis B virus replicates at a high rate. The viral-polymerase also lacks proofreading capability. These conditions result in the generation of a large number of viral mutations. Mutations that confer a replication advantage are preferentially selected under pressure from antiviral therapy. Mutations in the reverse transcriptase/polymerase domain confer resistance to nucleoside analogues.

Lamivudine has the lowest genetic barrier to the development of resistance. After 4 years of treatment with lamivudine, 71% of patients have developed the M204V/I mutation, which renders this drug ineffective. Twenty-two percent of individuals treated with telbivudine develop this mutation after 2 years of therapy. With adefovir, about 29% of patients have developed an N236T mutation after 5 years of treatment. Resistance has not been reported with TDF. The rate of resistance with entecavir is 1% or less after 5 years in treatment-naive individuals, whereas in those with preexisting M204V/I mutation, the prevalence of resistance is much higher, 51% after 5 years (Bhattacharya and Thio, 2010; Ghany and Doo, 2009).

The emergence of resistance has important clinical consequences. Resistance leads to therapeutic failure and a rapid resurgence of viral replication. This resurgence in HBV replication may predispose patients to hepatic decompensation. For this reason, monotherapy with lamivudine, adefovir, or telbivudine is not recommended for the treatment of hepatitis B (Terrault et al., 2016a). Individuals taking these drugs require frequent monitoring of HBV DNA and counseling on the importance of excellent adherence to the daily therapy.

Hepatic Impairment: Implications for HBV Treatment

Prolonged suppression of HBV DNA production prevents disease progression in individuals with cirrhosis and aids reversal of liver damage. Although IFN can be used in individuals with compensated cirrhosis, it is contraindicated in those with decompensated cirrhosis. Nucleos(t)ide analogue therapy is the treatment of choice for decompensated disease (Martin et al., 2015). In general, nucleos(t)ide analogue treatment improves liver function and increases the 5-year survival rate in individuals with decompensated cirrhosis from 14%–35% to 55%–86% (Honda et al., 2015). It may also prevent the need for liver transplantation.

The nucleoside- or nucleotide analogues of choice for the treatment of decompensated cirrhosis are entecavir and TDF. Both agents require adjustments for renal impairment. TDF has been associated with nephrotoxicity, and entecavir has been associated with lactic acidosis in this population, so careful monitoring is imperative. Also, a combination of nucleoside- or nucleotide analogues may be needed to improve efficacy in those with preexisting viral resistance. All nucleoside- or nucleotide analogues carry a black-box warning for the risk of lactic acidosis, a risk that may be greater in individuals with advanced liver disease.

Pharmacotherapy of HBV Infection

Practice guidelines are available from several authorities on the treatment of HBV (Martin et al., 2015; Terrault et al., 2016; WHO, 2015). A description of current HBV therapies follows and a summary of the therapeutic uses and clinical pharmacology of these drugs is provided at the chapter’s end.

Interferons

Interferons are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative effects (Chapter 35). These proteins are synthesized by host cells in response to various inducers and, in turn, cause biochemical changes leading to an antiviral state in cells. Three major classes of human IFNs with significant antiviral activity currently are recognized: α (>18 individual species), β, and γ. Clinically used recombinant α-IFNs are nonglycosylated proteins of about 19,500 Da. Attachment of IFN proteins to large inert PEG molecules ( pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing. PegIFN-α is a first-line agent for the treatment of HBV.

Mechanisms of Action and Resistance. IFN-α may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin 1, interleukin 2, and tumor necrosis factor). IFN-α exhibits antiviral and antiproliferative actions, stimulates the cytotopic activity of lymphocytes, natural killer cells, and macrophages, and upregulates expression of class I MHC antigens and other surface markers. In addition, IFNs downregulate production of a number of cellular proteins, which may be an equally important mediator of the pharmacological benefit of IFNs (Teijaro, 2016).

Following binding to specific cellular receptors, IFNs activate the Jak-STAT signal transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes containing an IFN-specific response element. This, in turn, leads to synthesis of over two dozen proteins that contribute to viral resistance mediated at different stages of viral penetration.

Inhibition of protein synthesis is the major inhibitory effect for many viruses. IFN-induced proteins include 2–5(A) synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The 2–5(A) synthetase produces adenylate oligomers that activate a latent cellular endoribonuclease (RNase L) to cleave both cellular and viral single-stranded RNAs. The protein kinase selectively phosphorylates and inactivates a protein involved in protein synthesis, eIF-2. IFN-induced protein kinase also may be an important effector of apoptosis. In addition, IFN induces a phosphodiesterase that cleaves a portion of transfer RNA and thus prevents peptide elongation. A given virus may be inhibited at several steps, and the principal inhibitory effect differs amongst virus families.

Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects or by modifying the immune response to infection. For example, IFN-induced expression of MHC antigens may contribute to the antiviral actions of IFN by enhancing the lytic effects of cytotoxic T lymphocytes. Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage in certain viral diseases.

Host genetics may predict IFN responsiveness. Single-nucleotide polymorphisms (rs12979860 and rs12980275) on or near the IL-28B gene on chromosome 19 have been associated with decreased responsiveness to IFN therapy with hepatitis C treatment (Sonneveld et al., 2012). Data are conflicting on whether IL-28B genetics are associated with response to IFN in individuals with HBV (Martin et al., 2015). This gene encodes IFN-λ-3. INF-λ enhances and sustains effects of INF-α on viral replication.

ADME. Oral administration of IFN-α does not result in detectable IFN levels in serum or increases in 2–5(A) synthetase activity in peripheral blood mononuclear cells (used as a marker of IFN’s biologic activity). After intramuscular or subcutaneous injection of IFN-α, absorption exceeds 80%. Pegylated IFN-α is dosed subcutaneously once per week. The dose of pegIFN-α2a is 180 μg and should be reduced for patients with Cr (g) less than 30 mL/min. Plasma levels are dose related, peaking at 4–8 h and returning to baseline by 18–36 h. Levels of 2–5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 h and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 h and decreases slowly.
CHEMOTHERAPY OF INFECTIOUS DISEASES

reverse transcription of the negative strand from the pregenomic synthesis of the positive strand of HBV DNA

Although the frequencies of fever, nausea, injection site inflammation, such as zidovudine and ribavirin and may increase the neurotoxicity and is not established. IFNs can increase the hematological toxicity of drugs and uncommonly, cardio-vascular effects with hypotension and tachycardia. Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children (Sokal et al., 1998). The development of serum-neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility, and safety during pregnancy is not established. IFNs can increase the hematological toxicity of drugs such as zidovudine and ribavirin and may increase the neurotoxicity and cardiotoxic effects of other drugs. Thyroid function and hepatic enzymes should be monitored during IFN therapy.

PEGylated IFNs are generally better tolerated than standard IFNs, although the frequencies of fever, nausea, injection site inflammation, and neutropenia may be somewhat higher. Laboratory abnormalities, including severe neutropenia and the need for dose modifications, are higher in HIV-coinfected persons.

Pediatric and Geriatric Uses. Interferon-α2b is approved for children 1 year or older. The dose is 6 million IU/m² thrice weekly. PegIFN-α2a is not approved for children with HBV but is approved for treatment of children 5 years or older with HCV. Thus, the guidelines of the AASLD state that providers may consider using this drug in children with HBV (Terrault et al., 2016). The dose of pegIFN-α2a in children with chronic HCV is 180 μg/1.73 m² body surface area once weekly. PegIFN-α2a contains benzyl alcohol, which has been associated with neurologic toxicities in infants and neonates. Elderly patients may experience more toxicities from IFN treatment, and dose adjustments are necessary in renal impairment.

Entecavir

Entecavir is a guanosine analogue. Entecavir inhibited HBV DNA synthesis (50% reduction, EC50) at a concentration of 0.004 μM in human HepG2 cells transfected with wild-type HBV. The median EC50 value for entecavir against lamivudine-resistant HBV was 0.026 μM (range 0.010–0.059 μM).

Mechanisms of Action and Resistance. Entecavir requires intracellular phosphorylation. Entecavir triphosphate competes with endogenous deoxyguanosine triphosphate and inhibits all three activities of the HBV polymerase (reverse transcriptase):  
- base priming  
- reverse transcription of the negative strand from the pregenomic messenger RNA  
- synthesis of the positive strand of HBV DNA

Entecavir triphosphate is a weak inhibitor of cellular DNA polymerases α, β, and δ and mitochondrial DNA polymerase γ.

Susceptibility to entecavir is reduced with lamivudine and telbivudine resistance. In cell-based assays, 8–30-fold reductions in entecavir susceptibility were observed for lamivudine-resistant strains. In patients with preexisting lamivudine resistance, entecavir resistance emerged in 7% and 43% after 1 and 4 years, respectively.

Entecavir monotherapy in HIV/HBV-coinfected patients, including antiretroviral therapy-naive patients, has significant anti-HIV activity and can result in the development of the M184V variant (Sasadon et al., 2008). Thus, entecavir should only be used in combination with fully suppressive antiretroviral therapy in individuals with HIV/HBV co-infection.

ADME. The recommended dose for nucleoside-treatment-naïve adults without decompensated cirrhosis is 0.5 mg once daily. For adults with lamivudine or telbivudine resistance or for those with decompensated cirrhosis, the dose is 1 mg once daily. The dose must be reduced for individuals with CrCl less than 50 mL/min. Time to peak Cmax occurs in 0.5–1.5 h. Steady state is reached after 6–10 days of once-daily dosing. The tablet and oral solution can be used interchangeably. Administration with food decreases Cmax by 44%–66% and AUC by 18%–20%; thus, entecavir should be administered on an empty stomach.

Entecavir is extensively distributed in tissues and binds slightly (13%) to serum proteins. It is primarily eliminated unchanged in the kidney, probably by both glomerular filtration and net tubular secretion. Entecavir exhibits biphasic elimination, with a terminal t1/2 of 128–149 h. Dose reductions are needed for patients with CrCl less than 50 mL/min, typically by extension of the dosing interval.

Therapeutic Uses. Entecavir is FDA approved for the treatment of chronic HBV infection in adults and children 2 years or older with evidence of active viral replication and evidence of either persistent elevations in serum aminotransferases or histologically active disease. Entecavir is considered a first-line agent for HBV because of its potency, durability, and low genetic barrier to the development of resistance (Terrault et al., 2016). In HBsAg-positive individuals, 61% are viremically suppressed, 22%–25% have HBsAg loss, 68%–81% normalize ALT, and 4%–5% have HBsAg loss after 2–3 years of continuous entecavir treatment. In HBsAg-negative individuals, 90%–91% are viremically suppressed and
CHAPTER 63

TREATMENT OF VIRAL HEPATITIS (HBV, HCV)

78%–88% normalize ALT after 2–3 years of entecavir treatment, but fewer than 1% have HBsAg loss at 1 year. Entecavir reduces the risk of hepatocellular carcinoma relative to untreated historical controls. Few studies have shown a benefit to combination treatment of HBV; however, one study found that in individuals with HBV DNA of \(10^6\) or greater, the combination of entecavir and TDF was superior to entecavir alone (Lok et al., 2012). Nucleoside/tide combination therapy may also be used in the case of decompensated cirrhosis and in individuals with virologic breakthrough on entecavir or TDF. The safety of entecavir in pregnancy is unknown.

**Untoward Effects.** Severe acute exacerbations of HBV have been reported in patients who have discontinued anti-HBV therapy, including entecavir. Hepatic function should be monitored closely with both clinical and laboratory follow-up for at least several months in patients who discontinue anti-HBV therapy. There is a potential for development of resistance to nucleoside reverse transcriptase inhibitors in HBV/HIV coinfection, especially if HIV is not being treated. Lactic acidosis and severe hepatomegaly with steatosis may occur in patients with decompensated cirrhosis receiving entecavir. More common adverse reactions include headache, fatigue, dizziness, and nausea (Sasadeusz et al., 2008).

**Pediatric and Geriatric Uses.** Entecavir oral solution is approved in children older than 2 years and dosing is weight based up to 30 kg. Entecavir exposures following a single 1-mg dose were 29% higher in elderly versus young HBV-seronegative volunteers. This difference is likely explained by declines in renal function with age.

**Tenofovir**

Tenofovir, an acyclic nucleoside phosphonate, is available in two different prodrug formulations, TDF and TAF. TAF is described separately in a following discussion. With TDF, cellular esterases cleave the diester, yielding tenofovir in plasma, which enters cells and is subsequently phosphorylated by cellular kinases to tenofovir diphosphate (Figure 64–4). The drug has activity against both HIV-1 and HBV. In cell cultures in vitro, the EC\(_{50}\) for tenofovir against HBV ranges from 0.14 to 1.5 \(\mu\)M.

**Mechanisms of Action and Resistance.** The mechanism of action of tenofovir is presented in Chapter 64. Tenofovir has not been associated with the development of resistance when used as monotherapy for the treatment of HBV.

**ADME.** The TDF dose is 300 mg once daily; the dose is reduced in patients with renal impairment. The bioavailability of tenofovir is approximately 25%. Tenofovir exposures are increased 40% with a high-fat meal. Binding to plasma proteins is negligible (<8%). Tenofovir is not metabolized by CYP enzymes. The \(t_{1/2}\) of tenofovir in plasma is 17 h, and the \(t_{1/2}\) of the active form of the drug, tenofovir diphosphate, is 6-days and 17 days in peripheral blood and red blood cells, respectively. Tenofovir pharmacokinetics are not altered in hepatic impairment, but plasma exposures rise as Cl\(_{\text{Cr}}\) drops, becoming 2.8- and 7.3-fold higher in those with Cl\(_{\text{Cr}}\) of 30–49 mL/min and 12–29 mL/min compared to those with Cl\(_{\text{Cr}}\) greater than 80 mL/min. Doses should be reduced in those with Cl\(_{\text{Cr}}\) below 50 mL/min. Roughly 10% of the dose is removed by a 4-h hemodialysis session.

**Therapeutic Uses.** TDF is approved for the treatment of HBV infection in individuals 2 years or older. Due to its safety, efficacy, and resistance profile, TDF is a preferred agent for the treatment of HBV. In HBeAg-positive individuals, 76% are virologically suppressed, 21% have conversion from HBeAg to anti-HBe, 68% normalize ALT, and 8% have HBsAg loss after 3 years of continuous TDF treatment. In HBeAg-negative individuals, 93% are virologically suppressed and 76% normalize ALT after 2–3 years of treatment, but none have HBsAg loss at 1 year (Terrault et al., 2016).

Few studies have shown a benefit to combination treatment of HBV; however, one study found that in individuals with HBV DNA \(10^6\) or greater, the combination of entecavir and TDF was superior to entecavir alone (Lok et al., 2012). Nucleoside/tide combination therapy may also be used in the case of decompensated cirrhosis and in individuals with virologic breakthrough on entecavir or TDF. TDF has a pregnancy category of B, although a study found that infants born to HIV-infected women receiving TDF had 12% lower bone mineral density compared to infants born to women receiving other antiretroviral agents. HIV-infected individuals are generally treated with tenofovir and emtricitabine. Emtricitabine is a cytidine analog with activity against HIV and HBV. Refer to Chapter 64 for additional information about emtricitabine.

**Untoward Effects and Drug Interactions.** Tenofovir has a low potential for interactions but is not devoid of interactions. Tenofovir is a substrate for several membrane transporters, including OAT1 and MRP4, and TDF is a substrate for Pgp and BCRP and thus tenofovir may be affected by drugs that inhibit or induce these transporters. Some HCV therapies (e.g., sofosbuvir, ledipasvir, and velpatasvir) increase tenofovir exposures; patients receiving such combinations require more frequent renal monitoring.

**Pediatric and Geriatric Uses.** Primary considerations in treating the elderly with TDF are the bone and renal toxicities; a thorough study of TDF in the geriatric population has not been published. TDF has been studied in children and is approved for those 2 years or older. The dose of TDF in children is 8 mg/kg, with a maximum of 300 mg daily.

**Adefovir**

Adefovir dipivoxil is a diester prodrug of adefovir, an acyclic phosphate nucleoside analogue of adenosine monophosphate. Inhibitory concentrations of adefovir against HBV range from 0.2 to 1.2 \(\mu\)M in cell culture.

**Mechanisms of Action and Resistance.** Adefovir dipivoxil enters cells and is deesterified to adefovir. Adefovir is converted by cellular enzymes to the diphasphate, which acts as a competitive inhibitor of viral DNA polymerases and reverse transcriptases with respect to dATP and also serves as a chain terminator of viral DNA synthesis (Kundu, 1999).

Resistance to adefovir emerges in about 29% of patients after 5 years of treatment. The development of viral resistance may increase the risk of hepatic decompensation. Thus, adefovir, lamivudine, and telbivudine are not recommended for the treatment of HBV.

**ADME.** The adefovir dipivoxil dose is 10 mg once daily but must be reduced for those with renal impairment. The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine, liver, and blood to adefovir, providing a bioavailability of about 30%–60%. Food does not affect bioavailability. Adefovir is scantily protein bound (<5%) and has a volume of distribution of about 0.4 L/kg.

The drug is eliminated unchanged by the kidney through a combination of glomerular filtration and tubular secretion. After oral administration of adefovir dipivoxil, about 30%–45% of the dose is recovered within 24 h; the serum \(t_{1/2}\) of elimination is 5–7.5 h. The intracellular \(t_{1/2}\) of the active diphasphate form in vitro ranges from 5 to 18 h, although typically the half-lives are much longer in vivo. Dose reductions are recommended for Cl\(_{\text{Cr}}\) values below 30 mL/min. Adefovir is removed by hemodialysis, but the effects of peritoneal dialysis or severe hepatic insufficiency on pharmacokinetics are unknown.

**Therapeutic Uses.** Adefovir dipivoxil is approved for treatment of chronic HBV infections in individuals 12 years and older. However, adefovir dipivoxil is not a preferred agent for the treatment of HBV because it is associated with the development of viral resistance and nephrotoxicity.

**Untoward Effects and Drug Interactions.** Adefovir dipivoxil causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria, which usually are reversible months after discontinuation. Other adverse effects include headache, abdominal discomfort, diarrhea, and asthenia. Adverse events lead to premature discontinuation in about 2% of patients. After 2 years of dosing, the risk of serum creatinine levels rising above 0.5 mg/dL is approximately 2% but is higher in those with preexisting renal insufficiency. Acute, sometimes severe, exacerbations of hepatitis can occur in patients stopping adefovir or other anti-HBV therapies.
Close monitoring is necessary, and resumption of antiviral therapy may be required in some patients.

No clinically important drug interactions have been recognized to date, although drugs that reduce renal function or compete for active tubular secretion could decrease adefovir clearance. Ibuprofen increases adefovir exposure modestly. An increased risk of lactic acidosis and steatosis may exist when adefovir is used in conjunction with other nucleoside analogues or antitroviral agents. Adefovir is transported efficiently by renal tubular OAT1.

Adefovir is genotoxic, and high doses cause hepatotoxicity, lymphoid toxicity, and renal tubular nephropathy in animals. The diphosphate's inhibitory effects on renal adenyl cyclase may contribute to nephrotoxicity (Shoshani et al., 1999). Adefovir dipivoxil is not associated with reproductive toxicity, although high intravenous doses of adefovir cause maternal and embryotoxicity with fetal malformations in rats (pregnancy category C).

**Pediatric and Geriatric Uses.** Adefovir should be avoided in elderly patients due to the risk for nephrotoxicity. This drug is approved in children 12 years or older at the same dose as that used in adults.

**Lamivudine**

Lamivudine, the (−)-enantiomer of 2′,3′-dideoxy-3′-thiacytidine, is a nucleoside analogue that inhibits HIV reverse transcriptase and HBV DNA polymerase. Details of its mechanism of action, ADME, and drug interaction potential are described in Chapter 64. Lamivudine inhibits HBV replication in vitro by 50% at concentrations of 4–7 ng/mL.

**Mechanisms of Action and Resistance.** Cellular enzymes convert lamivudine to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination.

After 5 years of treatment, approximately 71% of patients develop resistance to lamivudine. Point mutations in the YMDD motif of HBV DNA polymerase result in a 40- to 104-fold reduction in the in vitro susceptibility (Ono et al., 2001). Lamivudine resistance confers cross-resistance to related agents, such as emtricitabine. Lamivudine-resistant HBV retains susceptibility to tenofovir and partially to adefovir and entecavir. Lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HBeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients.

**Therapeutic Uses.** Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children 2 years or older. However, lamivudine is not a preferred agent for the treatment of HBV because it is associated with a high rate of viral resistance. Nonetheless, lamivudine is still used in many parts of the world because it is cheaper than other therapies.

The lamivudine dose is 100 mg once daily. In adults, doses of 100 mg/d for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels in 41% or more of patients, and reductions in hepatic inflammation in more than 50% of patients. Seroconversion with antibody to HBeAg occurs in fewer than 20% of recipients at 1 year. In children 2–17 years of age, lamivudine (3 mg/kg/d to a maximum of 100 mg/d for 1 year) is associated with normalization of aminotransferase levels in about one-half and seroconversion to anti-HBe in about one-fifth of cases. (Jonas et al., 2002). If resistant variants do not emerge, prolonged therapy is associated with sustained suppression of HBV DNA, continued histological improvement, and an increased proportion of patients experiencing a loss of HBeAg and undetectable HBV DNA. Prolonged therapy is associated with an approximate halving of the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis (Liauw et al., 2004). However, the frequency of lamivudine-resistant variants increases progressively with continued drug administration. Consider dose reduction for patients with renal impairment.

**Untoward Effects.** At the doses used for chronic HBV infection, lamivudine generally is well tolerated. Aminotransferase rises after therapy occur in lamivudine recipients, and flares in posttreatment amonotransferase elevations (>500 IU/mL) occur in about 15% of patients after cessation.

**Pediatric and Geriatric Uses.** The dose of lamivudine for use in children 2–17 years old is 3 mg/kg/d to a maximum of 100 mg/d. Lamivudine is not associated with increased toxicities in the elderly.

**Tenofovir Alafenamide**

A different prodrug of tenofovir, TAF, is a phosphonate ester of tenofovir (Ray et al., 2016).

**Mechanisms of Action and Resistance.** The active ingredient of TAF is tenofovir, an inhibitor of HBV reverse transcriptase and HIV-1 reverse transcriptase. TAF is relatively more stable in the plasma than TDF; it is more rapidly metabolized by cellular kinases to the active triphosphate form, tenofovir 5′-triphosphate, which inhibits HBV DNA polymerase (reverse transcriptase) by competing with the natural substrate, thymidine 5′-triphosphate. Incorporation of tenofovir 5′-triphosphate into viral DNA causes chain termination.

Resistance to tenofovir emerges in about 22% of patients after 2 years of treatment. The development of viral resistance may increase the risk for hepatic decompensation. Thus, this drug, along with lamivudine and adefovir, is not recommended for the treatment of HBV.

**ADME.** The standard tenofovir dose is 600 mg once daily. The bioavailability of tenofovir is 68% (Zhou et al., 2006), and the drug is widely distributed into tissues. Food does not affect the pharmacokinetics of tenofovir. The drug is eliminated unchanged in the urine. Tenofovir concentrations decline biexponentially with an elimination t1/2 of 40–49 h. Patients with moderate- to severe renal dysfunction and those undergoing hemodialysis require dose adjustments.

**Therapeutic Uses.** Tenofovir is indicated for the treatment of chronic HBV in adult patients (≥16 years) with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease. Although tenofovir has superior efficacy compared with lamivudine and adefovir, its use is associated with the development of resistance. Thus, tenofovir is not a preferred agent for the treatment of HBV.

**Untoward Effects and Drug Interactions.** Tenofovir is generally well tolerated and safe. The most common adverse events resulting in tenofovir discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy. Elevations of creatine kinase activity, mostly asymptomatic grade 3–4, are more common in tenofovir-treated patients after 2 years of therapy. The risk of peripheral neuropathy is increased when tenofovir is used with INF-α, so this combination should be avoided.

**Pediatric and Geriatric Uses.** Tenofovir is not approved for children younger than 16 years. The primary consideration in treating geriatric patients with tenofovir is renal function.

**Telbivudine**

Telbivudine is a synthetic thymidine nucleoside analogue with activity against HBV DNA polymerase. In a cell culture model, the EC50 for inhibition of viral DNA synthesis by telbivudine was 0.2 µM. The U.S. manufacturer has ceased producing telbivudine.

**Mechanisms of Action and Resistance.** Telbivudine is phosphorylated by cellular kinases to the active triphosphate form, telbivudine 5′-triphosphate, which inhibits HBV DNA polymerase (reverse transcriptase) by competing with the natural substrate, thymidine 5′-triphosphate. Incorporation of telbivudine 5′-triphosphate into viral DNA causes chain termination.

Resistance to telbivudine emerges in about 22% of patients after 2 years of treatment. The development of viral resistance may increase the risk for hepatic decompensation. Thus, this drug, along with lamivudine and adefovir, is not recommended for the treatment of HBV.

**ADME.** The standard telbivudine dose is 600 mg once daily. The bioavailability of telbivudine is 68% (Zhou et al., 2006), and the drug is widely distributed into tissues. Food does not affect the pharmacokinetics of telbivudine. The drug is eliminated unchanged in the urine. Telbivudine concentrations decline biexponentially with an elimination t1/2 of 40–49 h. Patients with moderate- to severe renal dysfunction and those undergoing hemodialysis require dose adjustments.

**Therapeutic Uses.** Telbivudine is indicated for the treatment of chronic HBV in adult patients (≥16 years) with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease. Although telbivudine has superior efficacy compared with lamivudine and adefovir, its use is associated with the development of resistance. Thus, telbivudine is not a preferred agent for the treatment of HBV.

**Untoward Effects and Drug Interactions.** Telbivudine is generally well tolerated and safe. The most common adverse events resulting in telbivudine discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy. Elevations of creatine kinase activity, mostly asymptomatic grade 3–4, are more common in telbivudine-treated patients after 2 years of therapy. The risk of peripheral neuropathy is increased when telbivudine is used with INF-α, so this combination should be avoided.

**Pediatric and Geriatric Uses.** Telbivudine is not approved for children younger than 16 years. The primary consideration in treating geriatric patients with telbivudine is renal function.
concentrations of the active form, tenofovir diphosphate, are actually higher than those achieved with TDF.

**Therapeutic Uses.** TAF is used at a daily dose of 25 mg to treat HBV. Two studies have found TAF noninferior to TDF in terms of suppressed HBV DNA after 48 weeks of treatment with smaller declines in bone mineral density and eGFR.

**Untoward Effects and Drug Interactions.** TAF has similar efficacy to TDF with fewer adverse effects on BMD and kidney function (CI, eGFR, proteinuria). Common side effects of tenofovir include nausea, rash, diarrhea, depression, and weakness. HBV “flare up” can result from sudden discontinuation of the drug.

**Investigational Agents**

Current therapies provide a functional cure (i.e., a cure that mimics naturally acquired immunity off therapy) in a minority of patients, and none provides a complete cure because cccDNA persists in cells. Thus, hepatitis B disease is an area ripe for drug development. There are currently more than 30 compounds in development for the treatment of hepatitis B (Brahmania et al., 2016). Although most are in the early stages of development, there is tremendous promise for the treatment of this virus.

**Hepatitis C Virus**

**HCV Overview**

Two percent of the world’s population—approximately 150 million people—are infected with HCV. Africa and Central and East Asia have the highest prevalence of HCV. The majority of individuals infected with HCV, about 85%, will develop chronic infection, which may progress to cirrhosis (WHO, 2016). Approximately 6% of cirrhotic individuals will develop symptoms of decompensated liver disease (e.g., ascites, hepatic encephalopathy, or variceal bleeding) each year, and 4% will develop hepatocellular carcinoma. These long-term complications carry a high risk of mortality and generally occur more than 20 years after infection (Freeman et al., 2001). There are approximately 700,000 HCV-related deaths annually. Without effective treatment, this number is expected to increase over the next 20 years. HCV is the leading indication for liver transplantation (Chinnadurai et al., 2012).

**Genetic Heterogeneity of HCV**

Hepatitis C virus exhibits remarkable within- and between-subject genetic heterogeneity, which is a major obstacle to the development of a universal treatment and a universal preventive vaccine. Six HCV genotypes have been identified. HCV strains belonging to different genotypes differ at 30%–35% of nucleotide sites (Messina et al., 2015). Within each genotype, HCV is further classified into subtypes that differ at fewer than 15% of nucleotide sites. Amongst genotypes, transmissibility does not seem to differ, whereas the rate of disease progression and response to treatment with current therapies does differ. Globally, genotype 1 is most prevalent (Messina et al., 2015), followed by genotype 3. Genotypes 2, 4, and 6 together account for 25% of those living with HCV. Within the U.S., 75% of HCV isolates are genotype 1a or 1b, and the remainder are primarily genotype 2 or 3 (Zein et al., 1996). Individuals with subtype 1a tend to have higher relapse rates with certain HCV treatments compared with individuals with subtype 1b.

**The HCV Genome and Life Cycle**

The HCV genome consists of a positive-sense, single-stranded RNA, about 9600 nucleotides long, which encodes three structural proteins (core, E1, and E2); the ion channel protein p7; and six nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B) (Tang and Grise, 2009). HCV replicates entirely within the cytoplasm (Figure 63–3); it does not

---

**Figure 63–3  Hepatitis C life cycle.** Not all steps in the hepatitis C viral life cycle have been completely elucidated. This figure represents our current understanding. For further details, consult the following references: Ciesek and Manns, 2011; Dubuisson and Cosset, 2014; and Holmes and Thompson, 2015.
establish latency, and it is curable. Cure of HCV is synonymous with achieving an SVR. SVR is defined as having no measurable HCV RNA in the blood following the cessation of treatment. With current therapies, SVR is assessed 12 weeks following treatment cessation. Achieving SVR decreases the progression of liver disease and reduces liver-related and all-cause mortality.

HCV Drug Targets and Treatment Approach
For many years, HCV was treated with a prolonged regimen of subcutaneously administered IFN-α (or pegIFN-α) with or without the purine nucleoside analogue ribavirin. SVR rates with this therapy were low, and tolerability was poor. Now, several antivirals that directly target various steps in the HCV life cycle (so-called DAAs) are the mainstay of HCV treatment. DAAs are administered orally, have fewer side effects, are taken for a period of 8, 12, or 24 weeks, and achieve SVR rates of at least 90% in most patient populations. Use of pegIFN-α for the treatment of HCV has largely been replaced by DAAs, although ribavirin is still used in combination with DAAs to improve SVR rates in certain clinical scenarios.

Detailed knowledge of the HCV life cycle and the structures of HCV proteins has permitted development of targeted inhibitors of HCV replication and revolutionized pharmacotherapy of HCV infection. Available DAAs target three major sites in the HCV life cycle: the NS3 protease, the NS5B polymerase, and NS5A (Figure 63–3) (Ciesek and Manns, 2011; Dubuisson and Cosset, 2014; Holmes and Thompson, 2015). Inhibition of the NS3 protease prevents the cleavage of the viral polyprotein and formation of the replication complex. The NS5B enzyme is essential for HCV replication as it catalyzes the synthesis of the complementary minus-strand RNA and subsequent genomic plus-strand RNA. There are two types of NS5B RdRp inhibitors: nucleotide and nonnucleotide inhibitors. The nucleotide inhibitors are active site inhibitors, whereas the nonnucleoside inhibitors are allosteric inhibitors. Another target, NS5A, encodes a protein that appears essential to the replication machinery of HCV and critical in the assembly of new infectious viral particles (Gish and Meanwell, 2011). However, the specific functions of this protein have not been established.

Clinical Implications of HCV Resistance
On average, almost a trillion HCV particles are produced in an infected individual each day (Neumann et al., 1998). The HCV NS5B polymerase enzyme lacks a proofreading function and has relatively poor fidelity (Brown, 2009); therefore, there is a continuous generation of a large variety of spontaneous viral mutations. Thus, even untreated persons have HCV genomes that harbor preexisting RAVs. These naturally occurring RAVs may affect the chances of achieving a cure with DAA treatment.

The likelihood that a DAA will select for and allow outgrowth of viral populations carrying RAVs during treatment depends on several factors, including the DAAs genetic barrier to resistance (the number and type of base-pair mutations needed to result in amino acid substitutions that confer resistance), the level of drug exposure(s), and the viral fitness (replicative capacity) of the RAV (Lontok et al., 2015). Nucleotide NS5B polymerase inhibitors have a high genetic barrier to resistance; three or more RAVs are required for full resistance. In contrast, the nonnucleoside NS5B polymerase inhibitors, NS3 protease inhibitors, and NS5A inhibitors generally have a low genetic barrier to the development of resistance; that is, only one or two amino acid substitutions result in lack of drug efficacy. For drugs in these classes, there is swift emergence of RAVs during monotherapy. Thus, as with HIV treatment, HCV treatment requires a combination of agents to optimize viral suppression and protect against the development of resistance. Data are emerging on the impact of treatment-emergent NSSA RAVs on the likelihood of achieving SVR with current therapies. NSSA RAVs have been shown to persist for several years after treatment cessation, and some NSSA inhibitors suffer from broad cross-resistance at key positions (Q30R, L31M/V, Y93H/N).

Hepatic Impairment: Implications for HCV Treatment
The vast majority of HCV-infected individuals have at least a 90% chance of achieving SVR with current therapies. There are some groups, however, such as those with decompensated cirrhosis, who have lower rates of SVR. Treating those with decompensated cirrhosis and achieving SVR have been shown to improve MELD scores and reverse fibrosis, but benefits are not immediate. Data are needed to demonstrate the long-term benefits of achieving SVR in those with decompensated disease.

Studies indicated the optimal time to treat HCV is early in the course of illness. The risk of developing decompensated cirrhosis or hepatocellular carcinoma, requiring a liver transplant, or dying from HCV-related complications is significantly lower in those treated with minimal fibrosis compared to those treated once bridging fibrosis or cirrhosis has developed. Treating all patients early in the course of disease is challenging, however, because many patients with HCV are unaware of their disease. Others are aware of their disease and wish to be treated but cannot access the DAAs. Many payers are prioritizing those with more advanced disease for treatment because of the cost of the DAAs.

Pharmacotherapy of HCV
A description of current DAA therapies follows, and a summary of the therapeutic uses and clinical pharmacology of these drugs is provided in the Drug Facts table at the end of this chapter. The HCV field is rapidly evolving. Up-to-date information on testing, managing, and treating HCV can be found in guidelines from the AASLD and Infectious Diseases Society of America (http://www.hcvguidelines.org). An important aspect of treating HCV is identification and management of drug-drug interactions.
interactions with DAAs (see, for instance, Table 63–1). The University of Liverpool offers a free, comprehensive, and reliable web-based drug interactions resource (available at http://www.hep-druginteractions.org).

**Sofosbuvir**

Sofosbuvir is a prodrug based on a uridine analogue. In cells, sofosbuvir is metabolized to an active form (known as GS-461203) that competes with uridine triphosphate for incorporation into HCV RNA by NS5B polymerase.

**Mechanisms of Action and Resistance.** Sofosbuvir is a prodrug, a 5′ monophosphorylated uridine analogue on which the charges of the phosphate group are masked by groups that are readily removed in the cell. The active drug, generated in the host mammalian cell, inhibits HCV RNA polymerase. Figure 63–4 shows the cellular pharmacology of sofosbuvir.

Sofosbuvir provides a high barrier to the development of resistance, but the S282T RAV has been reported in patients who relapsed to sofosbuvir-based treatment. L159F, V321A, and C316N/H/F have also been observed (Lontok et al., 2015).

**ADME.** The dose of sofosbuvir is 400 mg taken once daily. The absolute bioavailability of sofosbuvir is estimated to be at least 80% based on recovery of sofosbuvir and its primary metabolite, GS-331007, following administration of a radiolabeled dose. A high-fat meal increases sofosbuvir’s AUC by 67%–91%, but, based on the drug’s high therapeutic index, the increased exposure is not thought to increase the likelihood of toxicities (Kirby et al., 2015). Sofosbuvir exhibits time-independent, near-linear pharmacokinetics across a range of doses. Sofosbuvir is 63% protein bound, whereas protein binding of the deesterified GS-331007 is minimal.

The primary metabolic route of sofosbuvir is hydrolysis to GS-331007. GS-331007 lacks antiviral activity and cannot be rephosphorylated. The majority of a sofosbuvir dose is converted to GS-331007 and eliminated in the urine via a combination of tubular secretion and glomerular filtration. Sofosbuvir AUC is increased 2.3-fold and 2.5-fold in patients with moderate and severe hepatic impairment (i.e., Child Pugh B and C), respectively, but GS-331007 AUC is unchanged. No dose adjustment is needed for this population; available data suggest sofosbuvir is safe and effective in individuals with decompensated cirrhosis when combined with appropriate DAAs (Charlton et al., 2015; Manns et al., 2015; Poordad et al., 2015).

![Figure 63–4  Cellular pharmacology of sofosbuvir. Some nucleoside analogues act as antiviral agents in infected cells, but first they must cross the plasma membrane and then be phosphorylated, starting at the 5′ position, a slow reaction catalyzed by nucleoside kinase. Use of a monophosphorylated nucleoside avoids the slow nucleoside kinase reaction, but the charge on the phosphate groups would greatly slow passage of the molecule across the plasma membrane. Sofosbuvir circumvents these issues by having a phosphate (red ellipse) at the 5′ position of the nucleoside analogue (blue ellipse), but masking the two negative charges of the phosphate group are masked by groups that are readily removed in the cell. The active drug, generated in the host mammalian cell, inhibits HCV RNA polymerase. The triphosphate (GS-461203) is the active form responsible for the antiviral activity of sofosbuvir. GS-461203 acts as a defective dNTP substrate and inhibits HBV RNA polymerase (NS5B); it may also act as a chain terminator. Dephosphorylation of GS-461203 yields a uridine analogue metabolite, GS-331007, that cannot be readily rephosphorylated, lacks antiviral activity, and exits the cell. Most (90%) of the drug-related material measured in plasma is GS-331007. UMP-CMPK, uridine/cytidine monophosphate kinase; NDPK, nucleoside diphosphate kinase; CatA, cathepsin A; hCE1, human carboxylesterase 1.](image-url)
In contrast, sofosbuvir and GS-331007 pharmacokinetics are affected by renal impairment. Sofosbuvir and GS-331007 AUC increased about 60% in those with eGFR 50–80 mL/min/1.73 m² and 2-fold in those with eGFR 30–50 mL/min/1.73 m². These exposures were safe and tolerated in prior studies, but significant increases in exposure are noted in patients with severe renal impairment (eGFR < 30 mL/min/1.73 m²) and ESRD requiring dialysis. Thus, sofosbuvir should not be used in patients with eGFR of less than 30 mL/min/1.73 m² or those with ESRD until more data are available on the safety and appropriate dosing of this drug in this population (Kirby et al., 2015). Sofosbuvir’s AUC is 60% higher in HCV-infected persons, and GS-331007 AUC is 39% lower compared with HCV-seronegative volunteers. The mechanism for this is unclear. The median terminal half-lives of sofosbuvir and GS-331007 are 0.4 and 27 h, respectively.

**Therapeutic Uses.** The NNSB polymerase region is well conserved across genotypes. Thus, sofosbuvir is active against all HCV genotypes. In individuals with genotype 1 HCV, 7 days of sofosbuvir monotherapy reduces HCV RNA by 4.65 logs (Lawitz et al., 2013). Sofosbuvir is used in combination with other DAAIs, including the NS3/4A protease inhibitor simeprevir, the purine nucleoside analogue ribavirin, and the NSSA inhibitors daclatasvir, ledipasvir, or velpatavir. The efficacy and tolerability of sofosbuvir in these combination therapies are described in subsequent sections.

**Untoward Effects and Drug Interactions.** There are no hallmark toxicities associated with sofosbuvir use. Side effects observed when sofosbuvir is administered as part of combination DAA treatment are described in the material that follows with the concomitant antiviral.

Sofosbuvir is not a CYP substrate, inhibitor, or inducer and therefore has a low potential for drug interactions. However, sofosbuvir is a substrate for the efflux transporters Pgp and BCRP and should not be used with potent inducers of these transporters (e.g., rifampin, St. John’s wort, phenytoin, carbamazepine). Sofosbuvir-containing DAA treatments have been associated with bradycardia, the requirement for pacemaker insertion, and fatal cardiac arrest in patients taking amiodarone. The mechanism(s) for this is unclear, but the interaction appears to be more pharmacodynamic rather than pharmacokinetic in nature (Regan et al., 2016). If the combination cannot be avoided, cardiac monitoring in an inpatient setting is advised for the first 48 h of sofosbuvir-based treatment, with daily heart rate monitoring for an additional 2 weeks.

**Pediatric and Geriatric Uses.** Sofosbuvir is not currently approved in children, but studies are ongoing. There are limited data on the use of DAAs in older patients. Ninety individuals 65 years or older received sofosbuvir in clinical trials. Response rates in these 90 individuals and in patients less than age 65 were similar. Because sofosbuvir is renally cleared, renal function is the primary consideration in treating the geriatric population with sofosbuvir.

**Ribavirin**

Ribavirin, a purine nucleoside analogue with a modified base and D-ribose sugar, inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxovir-, paramyxovir-, arenavir-, bunyavir-, and flaviviruses in vitro.

**Mechanisms of Action and Resistance.** Host cell enzymes phosphorylate ribavirin to mono-, di-, and triphosphate derivatives. The exact mechanism(s) of action of ribavirin or its phosphorylated derivatives in vivo are unknown, but several immunomodulatory and antiviral effects have been observed in vitro, including (1) inhibiting the HCV RdRp, (2) depleting GTP (and thus nucleic acid synthesis in general) through inhibition of inosine 5’-monophosphate dehydrogenase, (3) enhancing viral mutagenesis, (4) converting the T-helper cell phenotype from 2 to 1, (5) inducing IFN-stimulated genes, and (6) modulating natural killer cell response. Ribavirin may select for HCV resistance mutations in vitro, but this has not been observed in vivo.

**ADME.** For the treatment of HCV, oral ribavirin dosing is weight based. Individuals weighing less than 75 kg receive 1000 mg daily in two divided doses. Individuals weighing at least 75 kg receive 1200 mg daily in two divided doses. Dose reductions are necessary for those with renal impairment, and individuals with renal impairment or decompensated cirrhosis may have difficulty tolerating 1000 or 1200 mg of ribavirin.

With aerosol administration, levels in respiratory secretions are very high but variable. Some systemic absorption occurs with aerosol administration (Cₚ after 3–4 days of dosing < 8% of Cₚ₀ seen with oral dosing). When administered orally, bioavailability averages 50%. Food increases plasma levels substantially. Ribavirin is a substrate for equilibrative and concentrative nucleoside uptake transporters (ENT1 [SLC29A1], CNT2 [SLC28A2], and CNT3 [SLC28A3]) and thus is widely distributed throughout the body. The half-lives of the mono-, di-, and triphosphate derivatives in red blood cells and peripheral blood mononuclear cells mirror the plasma t₁/₂ of parent ribavirin (7–10 days) (Wu et al., 2015). Hepatic metabolism (deribosylation and hydrolysis to a triazole carboxamide) and renal excretion of ribavirin and its metabolites are the principal routes of elimination. The dose of ribavirin should be reduced in patients with renal impairment. Even with a reduced dose, patients with renal impairment have difficulty tolerating ribavirin.

**Therapeutic Uses.** Ribavirin can be administered orally and intravesically and by inhalation. The aerosolized form of ribavirin is used in the treatment of a variety of respiratory viruses, including respiratory syncytial virus. Intravenous ribavirin has been used to treat hemorrhagic fever and severe influenza. Additional information on the use of aerosolized and intravenous ribavirin can be found in Chapter 64. Oral ribavirin is used in combination treatment with DAAIs for the treatment of chronic HCV infection in certain scenarios (e.g., in combination with sofosbuvir for genotype 2 disease, with sofosbuvir and ledipasvir, daclatasvir, or velpatavir in the setting of decompensated cirrhosis, with grazoprevir/elasbavir in individuals with genotype 1a HCV and preexisting NSSA RAVs, and with ritonavir-boosted paritaprevir and ombitasvir with or without dasabuvir in patients with genotype 1a or 4 disease). The efficacy of ribavirin in combinations with these DAAs is described in subsequent sections.

**Untoward Effects and Drug Interactions.** Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of valves and tubing with ribavirin. Healthcare workers should use techniques to reduce environmental exposure. Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy category X). Balus intravenous infusion may cause rigors. Systemic ribavirin causes dose-related reversible hemolytic anemia, with associated increases in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. The ribavirin dose is often reduced when hemoglobin decreases to less than 10 g/dL or declines by more than 3 g/dL and discontinued if hemoglobin becomes less than 8.5 g/dL.

Anemia occurs in 5%–11% of patients receiving ribavirin in combination with DAAs (clinical trials of mostly noncirrhotic subjects); 18%–40% of patients postliver transplant or with decompensated cirrhosis receiving ribavirin with DAAs experienced anemia, many receiving ribavirin doses lower than the typical 1000–1200 mg daily. Two polymorphisms in the gene encoding inosine triphosphatase protect against ribavirin-induced hemolytic anemia; the frequency of the protective alleles in the general population is around 10%.

Other ribavirin toxicities include fatigue, cough, rash, and pruritus. Preclinical studies indicated that ribavirin is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. Ribavirin is present in higher amounts in sperm than plasma. Thus, ribavirin is contraindicated in men and women who are attempting conception and for up to 6 months following cessation of treatment. Ribavirin has minimal drug interactions but should not be used with the HIV nucleoside analogue didanosine. Ribavirin increases formation of the triphosphorylated form of didanosine, which raises the risk of mitochondrial toxicity (see Chapter 64).

**Pediatric and Geriatric Uses.** Ribavirin is indicated for the treatment of HCV in children 5 years and older. Doses range from 400 to 1200 mg daily depending on body weight, administered in two divided doses.
Specific pharmacokinetic evaluations for ribavirin in the elderly have not been performed. As with sofosbuvir, the primary consideration in treating older individuals with ribavirin is renal function. The dose of ribavirin should be reduced in those with an eGFR less than or equal to 50 mL/min/1.73 m².

**Ledipasvir**

Ledipasvir, an NSSA inhibitor, is available only as part of a fixed-dose combination tablet with the NSSB nucleotide polymerase inhibitor, sofosbuvir (LDV/SOF).

**Mechanisms of Action and Resistance.** Ledipasvir is an inhibitor of NSSA. Baseline NSSA RAVs were detected in 16% of the 2144 participants in the phase 2 and 3 studies of LDV/SOF (Sarrazin et al., 2016). For treatment-naïve patients, the presence of baseline NSSA RAVs does not reduce the likelihood of achieving SVR, but treatment-experienced patients with baseline NSSA RAVs achieve lower SVR rates compared with treatment-experienced patients with no baseline RAVs. NSSA RAVs are detected in the majority of patients who fail to respond to LDV/SOF treatment. These NSSA RAVs persist for at least 2 years and may affect the success of future HCV treatments.

**ADME.** Ledipasvir, 90 mg, is available as part of a fixed-dose combination tablet with sofosbuvir (German et al., 2016). This tablet is administered once daily without regard to meals. LDV/SOF should not be used in individuals with an eGFR less than 30 mL/min/1.73 m².

Ledipasvir absorption is pH dependent. Concomitant use of antacids, H₂ receptor antagonists, and PPIs is problematic. The bioavailability of ledipasvir in humans is unknown (30%–50% in rats, monkey, and dogs). Ledipasvir concentrations are similar when given fasted versus a high-fat (1000 kcal) meal. Ledipasvir is greater than 99.8% bound to human plasma proteins. Ledipasvir is primarily eliminated unchanged in the feces. Approximately 30% is metabolized via uncertain pathways. Ledipasvir pharmacokinetics are not significantly altered by hepatic or renal impairment, but because the drug is coformulated with sofosbuvir, limitations on use in those with renal impairment apply. The t½ of ledipasvir is 47 h. Ledipasvir AUC and Cmax are 24% and 32% lower in HCV-infected subjects, respectively, compared with HCV-seronegative volunteers.

**Therapeutic Uses.** LDV/SOF is FDA approved for individuals with HCV (genotype 1, 4, 5, and 6 disease), individuals coinfected with HIV, and those with decompensated cirrhosis. In vitro, ledipasvir has limited activity against genotype 3; its activity against genotype 2 is reduced by the highly present L31M RAV; thus, LDV/SOF is not recommended for this genotype.

The SVR rates with 12 weeks of LDV/SOF therapy were 96% and 99% in clinical trials of HCV treatment-naïve patients and 95% in treatment-experienced patients without cirrhosis. Treatment-experienced individuals with cirrhosis should be treated for either 24 weeks with LDV/SOF or 12 weeks with LDV/SOF plus ribavirin to improve the likelihood of achieving a cure. LDV/SOF for 12 weeks achieved an SVR rate of 95% in two studies with a small number of individuals with genotype 4 disease. SVR was 93% in 44 patients with genotypes 5 and 96% in 25 patients with genotype 6 receiving 12 weeks of LDV/SOF.

Treatment of individuals with HIV/HCV co-infection yielded similarly high SVRs. In treating patients with decompensated cirrhosis, ribavirin is added to LDV/SOF treatment to increase SVR rates, usually at a ribavirin dose of 600 mg daily due to poor tolerability of ribavirin in this patient population.

**Untoward Effects and Drug Interactions.** Amongst patients receiving 12 weeks of LDV/SOF in phase III clinical trials, 13%–14% reported fatigue and headache. The addition of ribavirin to LDV/SOF in cirrhotic patients increased the number and frequency of adverse effects. Ledipasvir relies on an acidic environment for optimal absorption; thus, gastric acid modifiers should be used with caution. In one large cohort, use of PPIs was found to be an independent predictor of relapse to LDV/SOF treatment (Terrault et al., 2016b). If gastric acid modifiers must be used, temporal separation is necessary with antacids (by 4 h); H₂ blocker and PPI doses should not exceed the equivalent of 40 mg famotidine twice daily and 20 mg omeprazole once daily. The omeprazole must be administered simultaneously with LDV/SOF in the fasted state. Like sofosbuvir, ledipasvir is a substrate for Pgp and BCRP and thus cannot be used with potent inducers of these transporters. The CYP3A inducer efavirenz reduces ledipasvir concentrations by 30%, and the pharmacokinetic enhancer cobicistat increases ledipasvir concentrations by 2-fold; given the rather high therapeutic index of ledipasvir, these changes are not expected to have clinical relevance. Ledipasvir inhibits Pgp and BCRP and may increase the concentrations of rosuvastatin via inhibition of BCRP; thus, this combination is not recommended. Ledipasvir increases the exposure to tenofovir, which may increase the risk of renal toxicity in HIV-infected individuals taking TDF with a boosting agent such as ritonavir or cobicistat. Use of TAF instead of TDF is an option for patients taking an antiretroviral regimen, which includes ritonavir or cobicistat (MacBrayne and Kiser, 2016).

**Pediatric and Geriatric Uses.** A pharmacokinetic trial of LDV/SOF is ongoing in 200 children ages 3–18 years (NCT02249182). The SVR rate was 98% in 100 adolescents ages 12–17 years receiving the FDA-approved adult dose of LDV/SOF with good tolerability. Age is not associated with ledipasvir exposures in population pharmacokinetic analyses over the range of 18 to 80 years. No differences in safety or efficacy have been observed between individuals 65 years and older and younger patients.

**Daclatasvir**

Daclatasvir is an NSSA inhibitor.

**Mechanism of Action and Resistance.** Daclatasvir binds to the N-terminus of NSSA and inhibits both viral RNA replication and virion assembly. The Y93H RAV is detected in most patients who fail DCV/SOF treatment. This variant has been shown to persist for several years after treatment cessation. The optimal re-treatment strategy for patients who fail with NSSA RAVs is under investigation.

**ADME.** Daclatasvir is available as 30-mg and 60-mg tablets. The standard dose of daclatasvir is 60 mg, but the dose should be reduced to 30 mg with strong CYP3A inhibitors and increased to 90 mg with moderate CYP3A inducers (Table 63–1). The absolute bioavailability of daclatasvir is 67%. A high-fat, high-calorie meal reduces daclatasvir exposure by 23%, but a low-fat meal has no effect. The drug is approved for administration without regard to meals. Daclatasvir is highly protein bound (99%).

Daclatasvir is metabolized by CYP3A and is therefore susceptible to the effects of potent inducers and inhibitors of this enzyme, but the drug itself does not appear to inhibit or induce any CYPs. Daclatasvir is a substrate for Pgp. Daclatasvir inhibits Pgp, BCRP, and OATP1B1/3 and thus may increase exposures of drugs that are substrates for these transporters. Total exposure to daclatasvir is about 37% lower in patients with Child Pugh B and C decompensated cirrhosis, but unchanged concentrations are unchanged, and no dose adjustment is needed in such patients. Daclatasvir AUC increases in those with ESRD; with an eGFR of 15–29 mL/min/1.73 m², AUC is roughly doubled. Given the high therapeutic index of daclatasvir, this change is unlikely to have clinical relevance. However, since daclatasvir is given with sofosbuvir, the restrictions in those with eGFR less than 30 mL/min/1.73 m² still apply. The half-life of daclatasvir is 12–15 h. Daclatasvir pharmacokinetics are similar in HCV-seropositive and -seronegative individuals.

**Therapeutic Uses.** Daclatasvir is FDA-approved for use in combination with sofosbuvir in those with genotype 3 disease, in individuals with HIV co-infection regardless of HCV genotype, and in persons with advanced liver disease (Keating, 2016). It is rarely used in the U.S., however, because there are coformulated and cheaper alternatives. In Japan, daclatasvir is also approved in combination with the HCV NS3/4A protease inhibitor asunaprevir; this combination is not available in the U.S.

The SVR rates are 86%–90% in treatment-naïve and treatment-experienced individuals receiving 12 weeks of DCV/SOF. Lower SVR rates occur in those with cirrhosis (63%). Thus, cirrhotic patients with genotype 3 disease may benefit from the addition of ribavirin. In HIV-coinfected
individuals with HCV genotypes 1–4. 96% achieved SVR with 12 weeks of daclatasvir and sofosbuvir administration. In a group of individuals primarily (75%) infected with HCV genotype 1 with advanced liver disease and with Child Pugh A (n = 12), B (n = 32), and C (n = 16) cirrhosis, 92%, 94%, and 56%, respectively, achieved SVR with 12 weeks of DCV/SOF plus ribavirin treatment.

**Untoward Effects and Drug Interactions.** Daclatasvir is well tolerated. The most commonly reported adverse effects in genotype 3 patients receiving DCV/SOF were headache and fatigue (14% each). HIV-coinfected patients reported fatigue (17%), nausea (13%), and headache (11%). When combined with ribavirin in patients with advanced cirrhosis, the most common adverse effects were anemia (20%), fatigue (18%), nausea (17%), and headache (15%).

Daclatasvir is primarily a victim rather than a perpetrator in drug-drug interactions (Garimella et al., 2016). Daclatasvir cannot be used with potent CYP3A4 inducers but may be used with moderate inducers, if the daclatasvir dose is increased from 60 to 90 mg. The daclatasvir dose must be reduced from 60 to 30 mg with potent CYP3A4 inhibitors. Table 63–1 lists some comedications necessitating a daclatasvir dose modification.

**Pediatric and Geriatric Uses.** Daclatasvir has not been evaluated in children or the elderly. Age was not significantly associated with daclatasvir pharmacokinetics in population modeling over the range 18–79 years; no unique safety concerns were evident in those over 65 years of age, and SVR rates were comparable in older and younger subjects in trials.

**Simeprevir**

Simeprevir is an inhibitor of the HCV NS3 protease. Simeprevir is a noncovalent peptidomimetic with a macrocyclic structure.

**Mechanisms of Action and Resistance.** Simeprevir is an inhibitor of the HCV NS3 protease. Inhibition of the NS3 protease prevents cleavage of the viral replication complex (NS4A-NS4B, NS4B-NS5A, and NS5A-NS5B) and thus prevents the formation of viral RNA. Patients that fail to respond to SIM/SOF therapy typically have either the R155K or D168E substitutions in the HCV NS3 protease. Inhibition of the NS3 protease prevents cleavage of sofosbuvir and 100 mg of VEL taken once daily. As with ledipasvir, VEL absorption is pH dependent, and gastric acid modifiers require special dosing considerations with this agent; food has little effect on VEL absorption. VEL is greater than 99.5% protein bound. VEL is predominately excreted in feces as parent and metabolite; less than 1% of a dose appears in urine. VEL AUC changes only modestly (−17% to +14%) with moderate and severe hepatic impairment. In patients with severe renal impairment (eGFR < 30 mL/min/1.73 m²), the AUC of VEL increases by 50%. Because VEL is used with sofosbuvir, the same limitations on use in those with eGFR less than 30 mL/min/1.73 m² apply. The VEL t½ is 15 h. VEL AUC and Cmax are reduced by ~40% in HCV-infected individuals compared with healthy volunteers.

**ADME.** Simeprevir is a fixed-dose combination tablet containing 400 mg of sofosbuvir and 100 mg of VEL taken once daily. As with ledipasvir, VEL absorption is pH dependent, and gastric acid modifiers require special dosing considerations with this agent; food has little effect on VEL absorption. VEL is greater than 99.5% protein bound. VEL is predominately excreted in feces as parent and metabolite; less than 1% of a dose appears in urine. VEL AUC changes only modestly (−17% to +14%) with moderate and severe hepatic impairment. In patients with severe renal impairment (eGFR < 30 mL/min/1.73 m²), the AUC of VEL increases by 50%. Because VEL is used with sofosbuvir, the same limitations on use in those with eGFR less than 30 mL/min/1.73 m² apply. The VEL t½ is 15 h. VEL AUC and Cmax are reduced by ~40% in HCV-infected individuals compared with healthy volunteers.

**Therapeutic Uses.** Simeprevir is the only currently available DAA combination therapy that is approved for the treatment of all HCV genotypes (1–6). SVR rates were 99% in patients with genotypes 1, 2, 4, 5, and 6 and 95% in genotype 3 patients with 12 weeks of VEL/SOF in trials. In decompensated patients, 83% achieved SVR with SOF/VEL for 12 weeks, 94% achieved SVR with SOF/VEL plus ribavirin, and 86% achieved SVR with 24 weeks of SOF/VEL.

**Untoward Effects and Drug Interactions.** The most common adverse effects from SIM/SOF are headache, fatigue, and nausea (11%–20%). Simeprevir contains a sulfonamide moiety and can cause photosensitivity, rash, and itching, more so in cirrhotic patients (5%, 16%, and 14%, respectively) receiving SIM/SOF. Simeprevir may elevate bilirubin levels. Higher simeprevir exposures have been associated with an increased frequency of the dermatologic events and bilirubin elevation.

Simeprevir is metabolized by CYP3A4 and should not be used with moderate or strong inducers or inhibitors of this enzyme. Simeprevir is a substrate for Pgp, MRPs, BCRP, OATP1B1/3, and OATP2B1. In terms of its ability to act as a perpetrator in interactions, simeprevir is a mild inhibitor of CYP1A2 and intestinal CYP3A and thus may increase the exposures of drugs metabolized by these enzymes. Simeprevir is also an inhibitor of the hepatic transporters OATP1B1, NTCP, Pgp, MRP2, and BSEP (see Chapter 5).

**Velpatasvir**

Velpatasvir is an NS5A inhibitor available as part of a fixed dose combination product with sofosbuvir (SOF/VEL).

**Mechanism of Action and Resistance.** Baseline RAVs do not appear to influence the likelihood of achieving SVR with SOF/VEL except in cirrhotic patients with genotype 3 disease where the SVR rate was 73% compared with 93% in those without baseline RAVs (Feld et al., 2015; Foster et al., 2015).

**ADME.** SOF/VEL is a fixed-dose combination tablet containing 400 mg of sofosbuvir and 100 mg of VEL taken once daily. As with ledipasvir, VEL absorption is pH dependent, and gastric acid modifiers require special dosing considerations with this agent; food has little effect on VEL absorption. VEL is greater than 99.5% protein bound. VEL is predominately excreted in feces as parent and metabolite; less than 1% of a dose appears in urine. VEL AUC changes only modestly (−17% to +14%) with moderate and severe hepatic impairment. In patients with severe renal impairment (eGFR < 30 mL/min/1.73 m²), the AUC of VEL increases by 50%. Because VEL is used with sofosbuvir, the same limitations on use in those with eGFR less than 30 mL/min/1.73 m² apply. The VEL t½ is 15 h. VEL AUC and Cmax are reduced by ~40% in HCV-infected individuals compared with healthy volunteers.

**Therapeutic Uses.** SOF/VEL is the only currently available DAA combination therapy that is approved for the treatment of all HCV genotypes (1–6). SVR rates were 99% in patients with genotypes 1, 2, 4, 5, and 6 and 95% in genotype 3 patients with 12 weeks of VEL/SOF in trials. In decompensated patients, 83% achieved SVR with SOF/VEL for 12 weeks, 94% achieved SVR with SOF/VEL plus ribavirin, and 86% achieved SVR with 24 weeks of SOF/VEL.

**Untoward Effects and Drug Interactions.** The most common adverse effects from SIM/SOF are headache, fatigue, and nausea (11%–20%). Simeprevir contains a sulfonamide moiety and can cause photosensitivity, rash, and itching, more so in cirrhotic patients (5%, 16%, and 14%, respectively) receiving SIM/SOF. Simeprevir may elevate bilirubin levels. Higher simeprevir exposures have been associated with an increased frequency of the dermatologic events and bilirubin elevation.

Simeprevir is metabolized by CYP3A4 and should not be used with moderate or strong inducers or inhibitors of this enzyme. Simeprevir is a substrate for Pgp, MRPs, BCRP, OATP1B1/3, and OATP2B1. In terms of its ability to act as a perpetrator in interactions, simeprevir is a mild inhibitor of CYP1A2 and intestinal CYP3A and thus may increase the exposures of drugs metabolized by these enzymes. Simeprevir is also an inhibitor of the hepatic transporters OATP1B1, NTCP, Pgp, MRP2, and BSEP (see Chapter 5).
and BCRP substrate) AUC increases about 170% when coadministered with VEL in healthy volunteers; digoxin (a Pgp substrate) AUC increases 34%. Single-dose rifampin, which acts as an OATP1B1 inhibitor, increases VEL AUC by 47%. However, multiple doses of rifampin, which induces CYP metabolism and transporter expression, reduces the AUC of VEL by about 82%. Single-dose cyclosporine (a mixed OATP1b1/Pgp/MRP2 inhibitor) doubles the VEL AUC. Ketoconazole (CYP3A inhibitor) increases the VEL AUC by 70%. Efavirenz reduces the VEL AUC by 50%, and this combination should be avoided.

**Pediatric and Geriatric Uses.** SOF/VEL has not been evaluated in children. Twelve percent of participants in phase III trials (156 subjects) were age 65 or older. No differences in efficacy or safety were observed in this group compared with those less than 65 years.

**Ritonavir-Boosted Paritaprevir, Ombitasvir, With or Without Dasabuvir**

Ombitasvir is an NS5A inhibitor. Dasabuvir is a nonnucleoside NS5B polymerase inhibitor. Paritaprevir is an NS3 protease inhibitor. Ritonavir is an inhibitor of CYP3A and is used as a pharmacokinetic enhancer to increase the exposures and decrease the dosing frequency for paritaprevir. Ritonavir has no activity against HCV. For more information on the clinical pharmacology of ritonavir, refer to Chapter 64.

**Mechanism of Action and Resistance.** Ombitasvir and paritaprevir inhibit NS5A and the NS3 protease, respectively. Dasabuvir binds non-competitively to the palm I site outside the NS5B polymerase active site, producing a conformational change in NS5B before the elongation complex is formed (Eltahla et al., 2015). Ribavirin is administered in combination with these DAA s in patients with genotype 1a disease to increase the likelihood of achieving SVR.

The SVR rates are not statistically different between patients with pre-existing NS3, NS5A, and NS5B RAVs to those without preexisting RAVs. The most prevalent treatment-emergent RAVs in patients with genotype 1a were R155K and D168V in NS3, M28T and Q30R in NS5A, and S56G in NS5B. In a trial, in which 21 individuals (95% genotype 1a) failed to achieve SVR on PrOD, 96% still had detectable NS5A RAVs at 2 years. The approach to re-treatment of patients who have failed NS5A-based therapy is not clear, but a small study of 15 patients showed 93% of individuals could be cured with PrOD plus sofosbuvir for 12 to 24 weeks. Results from a number of phase II and phase III trials provide useful information on the clinical application of DAA s and PrOD/PrO therapy (Eltahla et al., 2015; Hussaini, 2016; Krishnan et al., 2015).

**ADME.** Ritonavir-boosted paritaprevir and ombitasvir are coformulated. These agents are administered as two tablets once daily for a total daily dose of 100 mg ritonavir, 150 mg paritaprevir, and 25 mg ombitasvir. Dasabuvir is administered as one 250-mg tablet taken twice daily. These medications should be administered with a meal; moderate, and high-fat meals increase exposures of all four. On this regimen, accumulation is minimal for ombitasvir and dasabuvir and approximately 1.5- to 2-fold for ritonavir and paritaprevir. Protein binding is high (about 99%) for all four drugs. Ombitasvir is primarily metabolized by amide hydrolysis followed by oxidative metabolism. Paritaprevir is metabolized by CYP3A, ritonavir primarily by CYP3A and to a lesser extent by CYP2D6. Dasabuvir is metabolized primarily by CYP2C8 and to a lesser extent by CYP3A. Paritaprevir exposures are increased 62% and 945% in individuals with Child Pugh B and C cirrhosis, respectively.

Due to reports of hepatic decompensation, hepatic failure, and death in patients with advanced liver disease receiving PrOD, this combination should not be administered to patients with decompensated cirrhosis. Ombitasvir pharmacokinetics are not significantly altered in renal impairment, but to the extent that renal impairment may affect hepatic function, paritaprevir, dasabuvir, and ombitasvir exposures will increase with worsening renal function. PrOD has been studied in noncirrhotic, HCV-infected individuals with eGFR less than 30 mL/min/1.73 m2; high cure rates were achieved, but ribavirin was difficult to tolerate in the genotype 1a individuals, 65% of whom developed anemia. The plasma half-lives of PrOD components are as follows: ombitasvir about 23 h; paritaprevir, 5.5 h; ritonavir, 4 h; and dasabuvir, 5.8 h. There are inconsistent results on differences in pharmacokinetics of PrOD in HCV-seropositive versus -HCV-seronegative individuals; some studies indicated a decrease in exposures in HCV-seropositive persons, while others indicated no difference.

**Therapeutic Uses.** The PrOD combination is FDA-approved for the treatment of HCV genotype 1. PrOD is administered for 12 weeks to patients with genotype 1b regardless of cirrhosis status. However, in individuals with genotype 1a, ribavirin is used with PrOD in a 12-week regimen to increase the rate of SVR (from 90% to 97%). Treatment should be extended to 24 weeks in patients with genotype 1a with cirrhosis because it increases the rate of SVR from 91% to 96%.

Ritonavir-boosted paritaprevir and ombitasvir is used with ribavirin, but without dasabuvir, for 12 weeks for the treatment of individuals with genotype 4 disease.

The SVR rates are similar in individuals with HIV coinfection to those seen in individuals with HCV mono-infection. The primary consideration in the treatment of HIV-coinfected individuals with PrOD or PrO is avoidance of drug interactions. Efavirenz, rilpivirine, and regimens containing cobicistat or ritonavir can be problematic with this therapy (MacBrayne and Kiser, 2016).

**Untoward Effects and Drug Interactions.** The most commonly reported clinical adverse effects with PrOD include nausea (8%), pruritus (7%), insomnia (5%), and asthenia (4%). The frequency of these effects doubles with the addition of ribavirin.

The PrOD combination acts as both a victim and a perpetrator in a number of clinically significant drug interactions. The ritonavir booster prolongs the dwell time of paritaprevir but may necessitate lowering the dose of any concomitant agent that CYP3A4 also metabolizes. CYP2C8 metabolizes dasabuvir (as does CYP3A4 to a lesser degree); thus, inhibitors of CYP2C8 may elevate dasabuvir blood levels and are contraindicated during PrOD therapy. Ethinyl estradiol–containing contraceptives will elevate hepatic enzymes and should be avoided with PrOD or PrO therapy; progestin-containing contraceptives may be used. Vigilance is required in the identification, management, and avoidance of interactions with PrO and PrOD therapy for HCV. Refer to the product labeling and consult the Internet (http://www.hep-druginteractions.org) for up-to-date information on drug interactions with this DAA combination.

**Pediatric and Geriatric Uses.** A study of PrOD is ongoing in children (NCT02486406). Approximately 8% of patients in clinical trials of PrOD were age 65 or older. No differences in safety or efficacy were observed between these subjects and younger subjects.

**Grazoprevir/Elbasvir**

Grazoprevir is an NS3/4A protease inhibitor; elbasvir is an NS5A inhibitor. These drugs are available in a single fixed-dose combination tablet.

**Mechanism of Action and Resistance.** Grazoprevir and elbasvir are inhibitors of the NS3 and NS5A viral enzymes, respectively. In trials, pre-existing NS3 RAVs were detected in 57% and 19% of individuals with genotype 1a and 1b, respectively, but the presence of preexisting NS3 RAVs does not reduce the likelihood of high SVR rates. The presence of preexisting NS5A RAVs did reduce SVR rates in genotype 1a patients. SVR rates were 58% and 68% in genotype 1a treatment-naïve and treatment-experienced patients, respectively, with preexisting NS5A RAVs. Adding ribavirin and extending the treatment duration greatly increases SVR rates in patients with preexisting NS5A RAVs.

**ADME.** GZR/EBR is dosed as a single 100-mg/50-mg fixed-dose combination tablet taken once daily without regard to meals, although a high-fat meal will increase the AUC and Cmax of grazoprevir by 1.5- to 2.8-fold. The bioavailability of elbasvir is 30%; that of grazoprevir ranges from 10% to 40%. The t1/2 of grazoprevir is about 30 h. Elbasvir has a t1/2 of 23 h. Less than 1% of grazoprevir and elbasvir are renally eliminated. Both drugs are extensively (~99%) bound. Grazoprevir exposures are increased 62% in those with mild (Child-Pugh A) and 388% in those with moderate (Child-Pugh B) hepatic impairment relative to those with no hepatic impairment. Total concentrations of elbasvir are 24% and 14% lower in patients with...

</table>

The percentage of patients reporting any adverse event (~75%) was similar to studies of GZR/EBR in patients without renal impairment. More serious events occurred in these patients (15% vs. 3%), but many were not considered related to GZR/EBR treatment (Roth et al., 2015).

**Untoward Effects and Drug Interactions.** The most common side effects with GZR/EBR are headache (17%), fatigue (16%), and nausea (9%–15%). Higher exposures of grazoprevir are associated with liver function test elevations. Grazoprevir may increase bilirubin concentrations through inhibition of OATP1B1.

Grazoprevir is a substrate for CYP3A4, Pgp, and OATP1B1. OATP1B1 inhibitors and moderate/strong CYP3A and Pgp inducers (including efavirenz) are not recommended for coadministration with GZR/EBR. Elbasvir is a substrate for CYP3A4 and Pgp and an inhibitor of BCRP and Pgp.

**Pediatric and Geriatric Uses.** GZR/EBR has not been studied in children, and no dedicated studies have been performed in older patients. No age effect was observed in elbasvir pharmacokinetics in young (22–45 years) versus elderly (65–78 years) males; elderly females had a 33% higher elbasvir AUC compared with elderly men even after adjustment for body weight.

**Investigational Agents and the Future for Treatment of HCV**

Several agents are still in clinical development for the treatment of hepatitis C, including combination therapies such as sofosbuvir + velpatasvir + voxilaprevir (Lawitz et al., 2016a), glecaprevir + pibrentasvir (Gane et al., 2016), and MK-3682 + grazoprevir + ruzasvir. However, compared with 10 years ago, drug development has slowed. For those individuals able to access therapy, currently available agents achieve cure in most (but not all) patient populations. The remaining challenges for this disease are testing and diagnosis, linkage to care, increasing access to these expensive therapies, and management of special patient populations, including cirrhotic individuals with genotype 3 disease, individuals with decompensated cirrhosis, and those who fail DAA treatment.
**Therapeutic Uses**

- 12-week therapy in patients without cirrhosis
- Used in combination with other HCV regimens to boost therapeutic efficacy
- Preferred treatment in renal impairment

**Clinical Pharmacology and Tips**

- High potential for CYP-mediated drug interactions
- Should not be used with moderate and strong CYP3A and Pgp inducers
- Should not be used with OATP1B1 inhibitors
- Common adverse reactions: headache, fatigue, nausea

**Bibliography**

The pharmacotherapy of HIV infection is a rapidly moving field. Three-drug combinations are the current minimum standard of care for this infection, so available agents and formulations constitute several thousand possible regimens. Knowing the essential features of the pathophysiology of this disease and how chemotherapeutic agents affect the virus and the host is critical in developing a rational approach to therapy. Unique features of this drug class include the need for lifelong administration to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly.

Pathogenesis of HIV-Related Disease

Human immunodeficiency viruses are lentiviruses, a family of retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Replication is constant following infection, and although some infected cells may harbor nonreplicating virus for years, in the absence of treatment there generally is no true period of viral latency following infection (Deeks et al., 2015). Humans and nonhuman primates are the only natural hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is more closely related to SIV and is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar sensitivity to most antiretroviral drugs, although the NNRTIs are HIV-1 specific and have no activity against HIV-2.

Virus Structure

HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope that is derived from the host cell plasma membrane (Figure 64–1). The viral genome encodes three major open reading frames: gag encodes a polypeptide that is processed to release the major structural proteins of the virus; pol overlaps gag and encodes three important enzyme activities (an RNA-dependent RNA polymerase or reverse transcriptase with RNase activity, protease, and the viral integrase); and env encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include tat, rev, nef, and vpr.

Virus Life Cycle

Understanding the HIV life cycle (Figure 64–1) is crucial to understanding the rational therapy of HIV infection. HIV tropism is controlled by the envelope protein gp120 (env). The major target for env binding is the CD4 receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the chemokine receptors CCR5 or CXCR4. CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominantly the CCR5-tropic virus; HIV with this tropism is responsible for nearly all naturally acquired infections. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the increased affinity of HIV-1 for CXCR4 allows infection of T-lymphocyte lines. A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of CD4+ helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still unknown, but it is possible to develop clinical AIDS without this switch (Deeks et al., 2015).

The gp41 domain of env controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNA-DNA duplex; the original RNA is degraded by the RNase H activity of reverse transcriptase to allow creation of a full-length double-stranded DNA copy of the virus. Because the HIV reverse transcriptase is error prone and lacks a proofreading function, mutation is frequent and occurs at about three bases of every full-length (9300-base-pair) replication (Coffin, 1995). Virus-derived DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location (Greene and Peterlin, 2002).

Following integration, the virus may remain quiescent, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the viral DNA is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid. The envelope and structural proteins assemble at the cell surface, concentrating in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating new enveloped HIV particles containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into virus particles so replication can begin immediately after the virus enters a new cell.

How the Virus Causes Disease

Sexual acquisition of HIV infection is likely mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2–4 weeks, with 10^7 cells or more becoming infected. This peak is associated with a transient dip in the number of peripheral CD4+ (helper) T lymphocytes. As a result of new host immune responses and target cell depletion, the number of infectious virions as reflected by the plasma HIV RNA concentration (also known as viral load) declines to a quasi-steady state. This set point reflects the interplay between host immunity and the pathogenicity of the infecting virus.
**Abbreviations**

ABC: abacavir  
ADME: absorption, distribution, metabolism, excretion  
AIDS: acquired immunodeficiency syndrome  
5′-AMP: adenosine 5′-monophosphate  
AUC: area under plasma concentration-time curve  
cDNA: complementary DNA  
CL\(_{\text{cr}}\): creatinine clearance  
CMP: cytidine monophosphate  
CNS: central nervous system  
CSF: cerebrospinal fluid  
CYP: cytochrome P450  
dCMP: deoxycytidine monophosphate  
ddc: didanosine  
ddi: didanosine  
DF: disoproxil fumarate  
DRESS: drug reaction with eosinophilia and systemic symptoms  
d4T: stavudine  
\(e\text{CL}_{\text{cr}}\): estimated creatinine clearance  
env: envelope protein gp160  
FDA: Food and Drug Administration  
FTC: emtricitabine  
GI: gastrointestinal  
HBV: hepatitis B virus  
HIV: human immunodeficiency virus  
HTLV: human T-cell lymphotrophic virus  
IMP: inosine 5′-monophosphate  
InSTI: integrase strand transfer inhibitor  
IRIS: immune reconstitution inflammatory syndrome  
LRT: long terminal repeat  
NDP: nucleoside diphosphate  
NNRTI: nonnucleoside reverse transcriptase inhibitor  
NRTI: nucleos(t)ide reverse transcriptase inhibitor  
OATP: organic anion-transporting polypeptide  
Pi: protease inhibitor  
PK: pharmacokinetic  
PRPP: phosphoribosyl pyrophosphate  
QT: corrected cardiac QT interval  
RNase H: ribonuclease H  
RT: reverse transcriptase  
SIV: simian immunodeficiency virus  
f\(_{1/2}\): half-life of elimination  
TAF: tenofovir alafenamide  
TAM: thymidine analogue mutation  
3TC: lamivudine  
TDF: tenofovir disoproxil fumarate  
vRNA: viral RNA  
ZDV: zidovudine

(Coffin, 1995). In the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host CD4+ T-lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm\(^3\), there is an increasing risk of opportunistic diseases and, ultimately, death. Sexual acquisition of CCr5-tropic HIV-1 is associated with a median time to clinical AIDS of 8–10 years if the patient is not treated. Some patients, termed long-term nonprogressors, can harbor HIV for more than two decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetic and immune responses.

An important question relevant to treatment is whether HIV disease is a consequence of CD4+ lymphocyte depletion alone. Most natural history data suggest that this is true. Regardless, successful therapy is based on inhibition of HIV replication; interventions designed specifically to boost the host immune response without exerting a direct antiviral effect have had no reliable clinical benefit (Deeks et al., 2015).

**Principles of HIV Chemotherapy**

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly CD4+ T lymphocytes. The goal of therapy is to suppress virus replication as much as possible for as long as possible. The current standard of care is to use at least three drugs simultaneously for the entire duration of treatment (Department of Health and Human Services, 2016).

Two large randomized clinical trials found substantial clinical benefit from initiating antiretroviral therapy regardless of baseline CD4 count (INSIGHT START Study Group, 2015; TEMPRANO ANRS 12136 Study Group, 2015); thus, the current global standard of care is to offer treatment to all infected individuals whenever possible (World Health Organization, 2015). Increasing evidence also confirms the value of antiretroviral therapy in preventing transmission of the virus from person to person (Cohen et al., 2011).

Drug resistance remains a key problem. There is a high likelihood that all untreated infected individuals harbor viruses with single- amino-acid mutations that confer some degree of resistance to every known antiretroviral drug because of the high mutation rate of HIV and the tremendous number of infectious virions (Coffin, 1995). Thus, a combination of active agents is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis (see Chapter 60). Prolonged drug holidays may allow the virus to replicate anew, increasing the risk of drug resistance and disease progression; such breaks in treatment are associated with increased morbidity and mortality and are not generally recommended (Lawrence et al., 2003).

The expected outcome of initial therapy in a previously untreated patient is undetectable viral load (plasma HIV RNA < 50 copies/mL) within 24 weeks of starting treatment. Mathematical models of HIV replication suggest that three is the minimum number of agents required to guarantee effective long-term suppression of HIV replication without resistance (Muller and Bonhoeffer, 2003). However, earlier models may not adequately predict the effects of newer and more potent antiretrovirals.

In treatment-naive patients, a regimen containing a nonnucleoside plus two NRTIs is as effective as a regimen containing an additional nucleoside (Shafer et al., 2003), indicating the equivalence of these three-drug and four-drug regimens. Four or more drugs may be used simultaneously in patients harboring drug-resistant virus, but the number of agents a patient can take is limited by toxicity and inconvenience.

Failure of an antiretroviral regimen is defined as a persistent increase in plasma HIV RNA concentrations in a patient with previously undetectable virus, despite continued treatment with that regimen. This indicates resistance to one or more drugs in the regimen and necessitates a change in treatment. The selection of new agents is therefore informed by the patient’s treatment history and viral resistance testing. Treatment failure generally requires implementation of a completely new combination of drugs (Department of Health and Human Services, 2016). Adding a single active agent to a failing regimen is functional monotherapy if the patient is resistant to all other drugs in the regimen. The risk of failing a regimen also depends on the percentage of prescribed doses taken during a given period of treatment.

As antiretroviral therapy becomes more effective and easier to take, long-term toxicity of these drugs is of greater importance. Fortunately, several approved antiretroviral agents (lamivudine, emtricitabine, raltegravir, possibly dolutegravir) have essentially no clinically significant short-term or long-term toxicities. A potential concern that applies to all PIs and NNRTIs is clinically significant pharmacokinetic drug interactions. Most agents in these two drug classes can act as inhibitors...
and/or inducers of hepatic CYPs, other drug-metabolizing enzymes, and drug transporters (Pisciotti and Gallicano, 2001; see also Chapter 5). An increasingly recognized complication of initiating antiretroviral therapy is accelerated inflammatory reaction to overt or subclinical opportunistic infections or malignancies. This immune reconstitution inflammatory syndrome (IRIS) is most commonly seen when initiating therapy in individuals with low CD4 counts or advanced HIV disease. Infections commonly associated with IRIS include tuberculosis and other mycobacterial diseases, cryptococcosis, hepatitis virus infections, and Pneumocystis pneumonia (Manabe et al., 2007).

**Drugs Used to Treat HIV Infection**

**Nucleoside and Nucleotide Reverse Transcriptase Inhibitors**

**Overview**

HIV-encoded, RNA-dependent DNA polymerase, also called reverse transcriptase, converts viral RNA into proviral DNA, which is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogues or nonnucleoside inhibitors (Table 64–1). NRTIs prevent infection of susceptible cells but do not eradicate the virus from cells that already harbor integrated proviral DNA. Nearly all patients starting antiretroviral treatment do so with at least one agent from this class. Figure 64–2 shows the mechanism of action of NRTIs, which involves phosphorylation by host cells to the active inhibitory form. All but one of the drugs in this class (see structures in Figure 64–3) are nucleosides that must be triphosphorylated at the 5'-hydroxyl to exert activity. The sole exception, tenofovir, is a nucleotide monophosphate analogue that requires two additional phosphates to acquire full activity.

**Zidovudine**

Zidovudine is a synthetic thymidine analogue (Figure 64–3) with potent activity against a broad spectrum of retroviruses, including HIV-1, HIV-2, and HTLVs I and II. Zidovudine is active in lymphoblastic and monocyctic cell lines but has no impact on cells already infected with HIV. Zidovudine appears to be more active in activated than in resting lymphocytes because...
Mechanisms of Action and Resistance. Intracellular zidovudine is phosphorylated to zidovudine 5'-triphosphate. Zidovudine-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3'-hydroxyl group. The monophosphate competitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate formed. Zidovudine-triphosphate only weakly inhibits cellular DNA polymerase a but is a more potent inhibitor of mitochondrial polymerase γ. Because the conversion of zidovudine-monophosphate to diphosphate is inefficient, high concentrations of the monophosphate accumulate inside cells and may serve as a precursor depot for formation of triphosphate. As a consequence, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of triphosphate, and higher plasma concentrations of zidovudine do not increase intracellular triphosphate concentrations proportionately.

Resistance to zidovudine is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219. These mutations are referred to as TAMs because of their ability to confer cross-resistance to other thymidine analogues, such as stavudine. The M184V substitution in the reverse transcriptase gene associated with the use of lamivudine or emtricitabine greatly restores sensitivity to zidovudine (Kuritzkes, 2011). The combination of zidovudine and lamivudine produces greater long-term suppression of plasma HIV RNA than does zidovudine alone.

ADME. Zidovudine is absorbed rapidly and reaches peak plasma concentrations within 1 h. Table 64–2 summarizes the drug’s pharmacokinetic profile, which is not altered significantly during pregnancy; drug concentrations in the newborn approach those of the mother. Parent drug crosses the blood-brain barrier relatively well and also is detectable in breast milk, semen, and fetal tissue.

Untoward Effects and Drug Interactions. Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia; these symptoms usually resolve within a few weeks. Erythrocytic macrocytosis is seen in about 90% of patients but usually is not associated with anemia. Chronic zidovudine administration has been associated with nail hyperpigmentation. Skeletal muscle myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase γ. Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal.

Probenecid, fluconazole, atovaquone, and valproic acid may increase plasma concentrations of zidovudine, probably through inhibition of glucuronosyl transferases. Zidovudine is neither substrate nor inhibitor of CYPs. Zidovudine can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly.

Mechanisms of Action and Resistance. Intracellular stavudine is sequentially phosphorylated to form stavudine 5'-triphosphate. Like zidovudine, stavudine is most potent in activated cells, probably because thymidine kinase, which produces the monophosphate, is an S-phase–specific enzyme. Stavudine resistance is seen most frequently with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219, which are mutations associated with zidovudine resistance. Resistance mutations for stavudine appear to accumulate slowly. Cross-resistance to multiple nucleoside analogues has been reported following prolonged therapy (Martin et al., 2010).

the phosphorylating enzyme, thymidine kinase, is S-phase specific (Cihlar and Ray, 2010). Zidovudine is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission; it also was previously recommended for postexposure prophylaxis in HIV-exposed healthcare workers. Zidovudine is marketed in oral tablets, capsules, and solution as well as a solution for intravenous injection. Zidovudine is available in coformulated tablets with lamivudine or with lamivudine and abacavir.

**Mechanisms of Action and Resistance.**
1. Triphosphate competes with native nucleotides (shown is zidovudine 5′-triphosphate)

2. Incorporation and chain termination

-OO O OPPP

N– N+ N

N– N+ N

Figure 64–2  Mechanism of NRTIs. Zidovudine is depicted; Table 64–1 lists other agents in the NRTI class. Nucleoside and nucleotide analogues must enter cells and be phosphorylated to generate synthetic substrates for reverse transcriptase. The fully phosphorylated analogues block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3′-hydroxyl group.

**ADME.** Table 64–2 summarizes the agent’s pharmacokinetic data. Stavudine is well absorbed and reaches peak plasma concentrations within 1 h; bioavailability is not affected by food. The drug penetrates well into the CSF, achieving concentrations that are about 40% of those in plasma. Placental concentrations of stavudine are about half those of zidovudine. The drug undergoes active tubular secretion, and renal elimination accounts for about 40% of parent drug; thus, the dose should be adjusted in patients with renal insufficiency.

**Untoward Effects and Drug Interactions.** The most common serious toxicity of stavudine is peripheral neuropathy. Although this may reflect mitochondrial toxicity, stavudine is a less-potent inhibitor of DNA polymerase γ than either didanosine or zalcitabine, suggesting that other mechanisms may be involved. Stavudine is also associated with a progressive motor neuropathy characterized by weakness and in some cases respiratory failure, similar to Guillain–Barré syndrome.

Lactic acidosis and hepatic steatosis are associated with stavudine use and may be more common when stavudine and didanosine are combined. Acute pancreatitis is not highly associated with stavudine but is more common when stavudine is combined with didanosine than when didanosine is given alone. Of all nucleoside analogues, stavudine use is associated most strongly with fat wasting (lipoatrophy). Stavudine has fallen out of favor largely because of this toxicity.

Figure 64–3  Structures of NRTIs.
Stavudine is mainly renally cleared and is not subject to metabolic drug interactions. The incidence and severity of peripheral neuropathy may be increased when stavudine is combined with other neuropathic medications; thus, drugs such as ethambutol, isoniazid, phenytoin, and vincristine should be avoided. Combining stavudine with didanosine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis; therefore, these two drugs should not be used together. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly (Martin et al., 2010).

Lamivudine
Lamivudine is a cytidine analogue reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and HBV. Lamivudine is approved for HIV in adults and children 3 months or older. Lamivudine has been effective in combination with other antiretroviral drugs in both treatment-naive and experienced patients and is a common component of therapy, given its safety, convenience, and efficacy (Cihlar and Ray, 2010). Lamivudine is also approved for treatment of chronic hepatitis B.

**Mechanisms of Action and Resistance.** Lamivudine enters cells by passive diffusion and is sequentially phosphorylated to lamivudine 5′-triphosphate, which is the active anabolite. Lamivudine has low affinity for human DNA polymerases, explaining its low toxicity to the host. High-level resistance to lamivudine occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce in vitro sensitivity to lamivudine as much as 1000-fold. The M184V mutation...
restores zidovudine susceptibility in zidovudine-resistant HIV and also partially restores tenofovir susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011). This effect may contribute to the sustained virologic benefits of zidovudine and lamivudine combination therapy.

**ADME.** Table 64–2 summarizes the pharmacokinetic parameters for this drug. Lamivudine is excreted primarily unchanged in the urine; dose adjustment is recommended for patients with a creatinine clearance less than 50 mL/min. Lamivudine freely crosses the placenta into the fetal circulation.

**Untoward Effects and Precautions.** Lamivudine is one of the least-toxic antiretroviral drugs. Neutropenia, headache, and nausea have been reported at higher-than-recommended doses. Pancreatitis has been reported in pediatric patients. Because lamivudine also has activity against HBV, caution is warranted in using this drug in patients coinfected with HBV or in HBV-endemic areas: Abrupt discontinuation of lamivudine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

**Abacavir**

Abacavir, a synthetic purine analogue, is approved for the treatment of HIV-1 infection, in combination with other antiretroviral agents. Abacavir is available in a coformulation with zidovudine and lamivudine for twice-daily dosing and in a coformulation with lamivudine, or lamivudine and delatgravir, for once-daily dosing. Abacavir is approved for use in adults and pediatric patients 3 months or older, with dosing in the latter based on body weight.

**Mechanisms of Action and Resistance.** Abacavir is the only approved antiretroviral that is active as a guanosine analogue. It is sequentially phosphorylated in the host cell to carboxylic 5'-triphosphate, which terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 5'-hydroxyl group (Cihlar and Ray, 2010). Clinical resistance to abacavir is associated with four specific substitutions: K65R, L74V, Y115F, and M184V. In combination, these substitutions can reduce susceptibility by up to 10-fold. K65R confers cross-resistance to all nucleosides except zidovudine. The M184V mutation associated with lamivudine or emtricitabine resistance partially restores susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011).

**ADME.** Table 64–2 summarizes the pharmacokinetic parameters for this agent. The presence of food does not affect the oral bioavailability of abacavir. Abacavir is neither a substrate nor an inhibitor of CYPs. Its CsF/plasma AUC ratio is about 0.3.

**Untoward Effects and Drug Interactions.** The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity syndrome characterized by fever, abdominal pain, and other GI complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea); musculoskeletal complaints; headache; and paresthesias are less common. The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate discontinuation of the drug. Once discontinued for hypersensitivity, abacavir must never be restarted. The hypersensitivity syndrome (2%–9% of patients) results from a genetically mediated immune response linked to both the HLA-B*5701 locus and the M493T allele in the heat-shock locus Hsp70-Hom. The Hsp gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor necrosis factor α release after exposure of human lymphocytes to abacavir ex vivo (White et al., 2015). Abacavir should not be used in anyone known to carry the HLA-B*5701 locus (approximately 10% of Caucasians).

Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of ethanol (0.7 g/kg) increases the abacavir plasma AUC by 41% and prolongs the elimination t1/2 by 26%, possibly owing to competition for alcohol dehydrogenase, which produces the dehydro-metabolite of the drug (see Table 64–2).

**Tenofovir**

Tenofovir is a derivative of 5'-AMP that lacks a complete ribose ring; it is the only nucleotide analogue currently marketed for the treatment of HIV infection. Tenofovir is available as the disoproxil or alafenamide pro-drugs, which substantially improve oral absorption. Tenofovir is active against HIV-1, HIV-2, and HBV. TDF is FDA-approved for treating HIV infection in adults and children older than 2 years in combination with other antiretroviral agents and for the treatment of chronic hepatitis B in adults and children older than 12. It is also approved for HIV preexposure prophylaxis (in combination with emtricitabine) in adults at high risk of acquiring the infection. A new tenofovir oral prodrg, TAF, is FDA-approved for the treatment of HIV and HBV. Its advantages over TDF include lower dose and less renal and bone toxicity (Sax et al., 2015); it is currently available in coformulation with elvitegravir, cobicistat, and emtricitabine; rilpivirine and emtricitabine; or emtricitabine.

**Mechanisms of Action and Resistance.** Tenofovir disoproxil is hydrolyzed rapidly to tenofovir, which is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate, which is actually a triphosphate. The parent drug is a monophosphate (Figure 64–3) (Cihlar and Ray, 2010). The disposition of oral tenofovir alafenamide is similar, but it circulates largely as the uncleaved prodrg, which is taken up into cells and then converted to the parent nucleotide; as a consequence, circulating concentrations of tenofovir, which may contribute to renal toxicity, are much lower than produced by the disoproxil fumarate prodrg. Tenofovir diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerase α, polymerase β, and polymerase γ, which is the basis for its selective toxicity.

Specific resistance occurs with a K65R substitution that has been associated with clinical failure of tenofovir-containing regimens. Tenofovir sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to zidovudine or stavudine. The M184V mutation associated with lamivudine or emtricitabine resistance partially restores susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011).

**ADME.** Table 64–2 shows pharmacokinetic data for tenofovir. Following an intravenous dose, 70%–80% of the drug is recovered unchanged in the urine; thus, doses should be decreased in those with renal insufficiency. Tenofovir is not known to inhibit or induce CYPs.

**Untoward Effects and Drug Interactions.** Tenofovir generally is well tolerated, with few significant symptoms reported except for flatulence. Rare episodes of acute renal failure and Fanconi syndrome have been reported, and this drug should be used with caution in patients with preexisting renal disease. Tenofovir use is associated with small declines in eClcr, after months of treatment in some patients; because the dose needs to be reduced in renal insufficiency, renal function (creatinine and phosphorus) should be monitored regularly. Because tenofovir also has activity against HBV, caution is warranted in using this drug in patients coinfected with HBV: Abrupt discontinuation of tenofovir may be associated with a rebound of HBV replication and exacerbation of hepatitis. Tenofovir can increase the AUC of didanosine, and the two drugs should not be used together (Cihlar and Ray, 2010).

Tenofovir plasma concentrations are increased by 30%–50% if combined with the pharmacokinetic enhancers ritonavir or cobicistat due to inhibition of renal drug transporters. Similar effects are seen with the HBV NS5A inhibitors ledipasvir and velpatasvir (see Chapter 63). These combinations are generally well tolerated, without producing significant renal injury. However, acute renal insufficiency has been reported when TDF is combined with the oral nonsteroidal diclofenac.

**Emtricitabine**

Emtricitabine is a cytidine analogue that is chemically related to lamivudine and shares many of its properties. Emtricitabine is active against HIV-1, HIV-2, and HBV. The drug is FDA-approved for treating HIV infection in adults, children, and infants, in combination with other antiretroviral agents, and is available coformulated with tenofovir with or without efavirenz or with tenofovir, elvitegravir, and cobicistat. Emtricitabine is also
approved for HIV preexposure prophylaxis (in combination with tenofovir) in adults at high risk of acquiring the infection.

Mechanisms of Action and Resistance. Emtricitabine enters cells by passive diffusion and is sequentially phosphorylated to its active metabolite, emtricitabine 5’-triphosphate. High-level resistance to emtricitabine occurs with the same mutations affecting lamivudine (mainly M184I/V), although these appear to occur less frequently with emtricitabine. The M184V mutation restores sensitivity to zidovudine in zidovudine-resistant HIV and partially restores sensitivity to tenofovir in tenofovir-resistant HIV harboring the K65R mutation (Kuritzkes, 2011). The same K65R mutation confers resistance to emtricitabine and the other cytidine analogue lamivudine, as well as didanosine, stavudine, and abacavir.

ADME. Table 64–2 summarizes pharmacokinetic data for emtricitabine. Orally administered drug is absorbed rapidly and well; the drug can be taken without regard to meals. Emtricitabine is excreted primarily unchanged in the urine; thus, the dose should be reduced in patients with CrCl below 50 mL/min.

Untoward Effects and Drug Interactions. Emtricitabine is one of the least-toxic antiretroviral drugs and has few significant adverse effects (Cihlar and Ray, 2010). Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Because emtricitabine also has in vitro activity against HBV, caution is warranted in using this drug in patients coinfected with HBV and in regions with high HBV seroprevalence; abrupt discontinuation of emtricitabine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to known metabolic drug interactions.

Didanosine
Didanosine (2’,3’-dideoxyinosine) is a purine nucleoside analogue that is active against HIV-1, HIV-2, and other retroviruses, including HTLV-1. The drug is FDA-approved for adults and children with HIV infection in combination with other antiretroviral agents. Didanosine is no longer widely prescribed because of the availability of agents with less toxicity (Martin et al., 2010).

Mechanisms of Action and Resistance. Didanosine enters cells via a nucleoside transporter and is sequentially phosphorylated by cellular enzymes to the triphosphate, the active anabolite that functions as an antiviral adenosine analogue. Resistance to didanosine is associated with mutations at reverse transcriptase codons 65 and 74. The L74V substitution, which reduces susceptibility 5- to 26-fold in vitro, is seen most commonly in patients failing to respond to didanosine (Kuritzkes, 2011). Other nucleoside analogue mutations, including TAMs, can contribute to didanosine resistance even though the drug does not appear to select for these mutations de novo. The reverse transcriptase insertion mutations at codon 69 produce cross-resistance to all current nucleoside analogues, including didanosine.

ADME. Table 64–2 summarizes major pharmacokinetic parameters for didanosine. The drug is acid labile and thus is administered with an antacid buffer. Food decreases didanosine bioavailability; all formulations of didanosine must be administered at least 30 min before or 2 h after eating. This complicates dosing of didanosine in combination with antiretroviral drugs that must be given with food, as is the case for most HIV PIs. Didanosine is excreted by glomerular filtration and tubular secretion; doses therefore must be adjusted in patients with renal insufficiency.

Untoward Effects and Drug Interactions. The most serious toxicities associated with didanosine include peripheral neuropathy and pancreatitis, both of which are thought to be a consequence of mitochondrial toxicity. Didanosine should be avoided in patients with a history of pancreatitis or neuropathy. Patients complain of pain, numbness, and tingling in the affected extremities. If the drug is stopped as soon as symptoms appear, the neuropathy should improve or resolve. However, irreversible neuropathy can occur with continued use. Retinal changes and optic neuritis also have been reported. Coadministration of other drugs that cause pancreatitis or neuropathy (i.e., stavudine) will increase the risk and severity of these symptoms. Ethambutol, isoniazid, vincristine, cisplatin, and pentamidine should be avoided. Serious hepatic toxicity occurs rarely but can be fatal (Martin et al., 2010). Other reported adverse effects include elevated hepatic transaminases, headache, and asymptomatic hyperuricemia; noncirrhotic portal hypertension can occur years after exposure to didanosine.

Buffering agents included in didanosine formulations can interfere with the bioavailability of some coadministered drugs because of altered pH or chelation with cations in the buffer. For example, didanosine greatly reduces the AUCs of ciprofloxacin and indinavir; concentrations of ketoconazole and itraconazole, whose absorption is pH dependent, also are diminished. These interactions generally can be avoided by separating administration of didanosine from that of other agents by at least 2 h after or 6 h before the interacting drug. The enteric-coated formulation of didanosine does not alter ciprofloxacin or indinavir absorption. Didanosine is excreted renally, and shared renal excretory mechanisms provide a basis for interactions with oral ganciclovir, allopurinol, and tenofovir. Methadone decreases the didanosine AUC by about 60%.

Nonnucleoside Reverse Transcriptase Inhibitors

Overview
The NNRTIs include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase, in a site distant from the active site (Figure 64–5). These compounds induce a conformational change in the 3-dimensional structure of the enzyme that greatly reduces its activity, and thus they act as noncompetitive inhibitors. Because the binding site for NNRTIs is virus-strain specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection. These compounds also have no activity against host cell DNA polymerases (de Bethune, 2010). The five approved NNRTIs are nevirapine, efavirenz, etravirine, rilpivirine, and delavirdine. Table 64–3 summarizes their pharmacokinetic properties.

In this class share a number of properties. All approved NNRTIs are eliminated from the body by hepatic metabolism. Efavirenz, etravirine, and nevirapine are moderately potent inducers of hepatic drug-metabolizing enzymes, including CYP3A4; delavirdine is mainly a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds. All NNRTIs except etravirine and rilpivirine are susceptible to high-level drug resistance caused by single-amino-acid changes in the NNRTI-binding pocket (usually in codons 103 or 181; Kuritzkes, 2011). Exposure to even a single dose of nevirapine in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients (Eshleman et al., 2004). These agents are potent and highly effective but should be combined with other active agents to avoid resistance. NNRTIs should never be used as single agents in monotherapy or as the sole addition to a failing regimen.

The use of efavirenz or nevirapine in combination with other antiretroviral drugs is associated with favorable long-term suppression of viremia and elevation of CD4+ lymphocyte counts. Rashes occur frequently with all NNRTIs, usually during the first 4 weeks of therapy. Rare cases of potentially fatal DRESS or Stevens-Johnson syndrome have been reported with nevirapine, efavirenz, rilpivirine, and etravirine. Fat accumulation can be seen after long-term use of NNRTIs, and fatal hepatitis has been associated with nevirapine use (de Bethune, 2010).

Nevirapine
Nevirapine is a dipyridohezapine NNRTI with potent activity against HIV-1. The drug is FDA-approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents. Nevirapine is approved for use in infants and children 15 days old or older, with dosing based on body surface area. Single-dose nevirapine was used widely in pregnant HIV-infected women to prevent mother-to-child transmission, but this practice is declining as more pregnant HIV-infected women are being placed on permanent multidrug antiretroviral regimens (de Bethune, 2010).
ADME. Table 64–3 summarizes the pharmacokinetic data for this agent. The drug readily crosses the placenta and has been found in breast milk. Nevirapine is a moderate inducer of CYPs and induces its own metabolism. To compensate for this, the drug should be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have occurred.

Untoward Effects and Drug Interactions. The most frequent adverse events associated with nevirapine are rash (in ~ 16% of patients) and pruritus. In most patients, the rash resolves with continued administration of drug; administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with nevirapine use, and this may be more common in women with CD4 counts greater than 250 cells/mm$^3$, especially during pregnancy (de Bethune, 2010). Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

Because nevirapine induces CYP3A4, this drug may lower plasma concentrations of coadministered CYP3A4 substrates. Methadone withdrawal has been reported in patients receiving nevirapine, presumably as a consequence of enhanced methadone clearance. Plasma ethinyl estradiol and norethindrone concentrations decrease by 20% with nevirapine; alternative methods of birth control are advised.

Efavirenz
